Measles	Live attenuated virus (available in monovalent form or combined with rubella [MR] or mumps [MMR])	Primary: 2 doses; see text for interval between doses Booster: none	Persons born after 1956 who have not had documented measles infection or have not received 2 doses of live measles vaccine	I—contraindicated (HIV not a contraindication) H—eggs or neomycin	Temperature of $\geq 39.4^{\circ}\text{C}$ , 5–21 days after vaccination, in 5%–15%; transient rash in 5%; 4%–55% have a local reaction
Mumps	Live attenuated virus	Primary: 1 dose (usually given as part of MMR vaccine) Booster: none	Persons born after 1956 who have not had documented mumps	H—eggs or neomycin	Mild allergic reactions uncommon; rarely parotitis
Poliomyelitis	Live attenuated virus, trivalent	Primary: 3 doses PO, the first 2 given at 6- to 8-wk intervals, the 3rd, 8–12 mo later Booster: 1 dose PO	Children and adolescents <18 yr Boost previously immunized persons; complete series in partially immunized adults; alternative to inactivated poliomyelitis vaccine in previously unimmunized adults when there is <1 mo before travel	Immunocompromised contacts of recipients; not used for primary immunization in persons >18 yr	Rarely paralysis
Poliomyelitis	Inactivated virus, trivalent; enhanced potency	Primary: 2 doses at 4- to 8-wk intervals; 3rd dose 6–12 mo after 2nd dose Booster: 1 lifetime dose	Preferred for persons 18 yr and older and for immunocompromised hosts*	P—safety unknown H—streptomycin or neomycin	Mild local reaction
Rubella	Live attenuated virus	Primary: 1 dose (usually given as part of MR or MMR) Booster: none	All persons, particularly women of childbearing age, without documented illness or live vaccine on or after 1st birthday	H—neomycin P—contraindicated I—contraindicated	Up to 40% postpubertal females have joint pains, transient arthritis, beginning 3–25 days after vaccination, persisting 1–11 days; frank arthritis in <2%
Tetanus–diphtheria (Td)	Adsorbed toxoids	Primary: 2 doses (0.5 mL) IM, 4–8 wk apart; 3rd dose 6–12 mo later Booster: every 10 yr	All adults	P—first trimester contraindicated Hypersensitivity or neurologic reaction to previous doses; severe local reaction	Local reactions; occasional fever, systemic symptoms Arthus-like reactions in persons with multiple previous boosters; rarely systemic allergy

Continued

Table 120-2 Immunizations for International Travel—cont'd

Vaccine	Type	Schedule	Indications	Precautions and Contraindications	Side Effects
Varicella	Live attenuated virus	Primary: 2 doses 4–8 wk apart Booster: ?	Persons without a history of varicella	P, I—contraindicated H—neomycin	Fever (10%), rash (8%); local reaction (25%–30%)
Yellow fever	Live attenuated virus	Primary: 1 dose (10 days to 10 yr before travel) Booster: every 10 yr	As required by individual countries	P—only high-risk travel Prudent to avoid vaccinating infants <9 mo I—contraindicated H—eggs P—safety unknown	Mild headache, myalgia, fever, 5–10 days after vaccination (2%–5%); rarely immediate hypersensitivity  Local reactions, fever (2%)
Meningococcal (A, C, Y, W-135)	Polysaccharide Conjugate	Primary: 1 dose Booster: 3–5 yr Primary: 1 dose Booster: 8 yr (?)	Required for entry into Saudi Arabia during the hajj (see <b>Recommended</b> )		
Recommended Cholera, oral <sup>†</sup>	Live attenuated (Mutachol Berna) Phenol-killed <i>Vibrio cholerae</i> ( $4 \times 10^9$ /mL)	Primary: 2 sachets PO once Booster: at 6 mo Primary: 2 doses 1 wk–1 mo apart at least 6 days before travel Booster: 6 mo	Health-care and aid workers in endemic areas  As required by individual countries	P—contraindicated  P—safety unknown Previous severe local or systemic reaction	Gastrointestinal upset  Local reaction of pain, erythema, and induration lasting 1–2 days; occasional fever, malaise
Encephalitis, tick	Killed vaccine available in Europe				
Encephalitis, Japanese	Inactivated	Primary: once weekly for 3 doses Booster: 1 dose at 12–18 mo; then every 4 yr Primary: 1 dose IM; 2nd dose at 6–12 mo Booster: 10+ yr	Rural areas >4 wk in risk areas of Asia and Southeast Asia  Travelers to risk areas	P—avoid in pregnancy unless high-risk travel H—allergic reaction to prior doses (thimerosal)  P—safety data not available; immunize according to risk H—2-phenoxylethanol P—safety data not available; immunize according to risk H—neomycin P—not a contraindication in high-risk persons	Local reactions (20%), systemic reactions (10%); allergic reactions: angioedema, urticaria (0.1%)  ~50% have mild local reactions ~3%–10% have mild systemic reactions (headache, malaise)  ~50% have mild local reactions ~3% have mild systemic reactions (fever, fatigue, abdominal pain) 10%–20% have mild local reactions; occasional mild systemic reactions (fever, headache, fatigue)
Hepatitis A	Inactivated viral (Havrix) SB		Travelers to risk areas		
	Inactivated (Vaqta) MF	Primary: 1 dose IM; 2nd dose at 6 mo Booster: 10+ yr	Travelers to risk areas		
Hepatitis B <sup>‡</sup>	Recombinant-derived hepatitis B surface antigen (Recombivax HB), MF (Engerix-B), SB	Primary: 2 doses 1 mo apart; 3rd dose 5 mo after second Booster: not recommended	Health-care workers in contact with blood; persons residing for >6 mo in areas of high endemicity for hepatitis B surface antigen; others at risk for contact with blood, body fluids, or potentially contaminated medical or dental instruments		

Combined hepatitis A/B	Inactivated viral A and recombinant B surface antigen (Twinrix) SB	Primary: 2 doses 1 mo apart; dose 3, 5 mo after second Booster: 10 yr + Travel of <3 mo duration: 0.02 mL/kg Travel 4–6 mo: 0.06 mL/kg	As for hepatitis A and B (Havrix and Engerix B)	As for hepatitis A and B (Havrix and Engerix B)
Immune globulin	Fractionated immune globulins	For short-term prevention of hepatitis A when travel is imminent		Transient local discomfort; rare systemic reaction
Meningococcal Pneumococcal	See <b>Required</b> Capsular Polysaccharide	Primary: once Booster: none		
Plague	Inactivated	Primary: 2 doses 4 wk apart; dose 3 is given 3–6 mo after dose 2 Booster: 2 doses 6 mo apart; thereafter 1 dose every 1–2 yr Preexposure: days 0, 7, and 21 or 28 Booster: depends on risk category and based on serologic testing	P—no studies available Not recommended P—unknown	Local reactions (71%); rarely fever, arthritis, rash, urticaria, serum sickness Mild local reactions; repeated doses produce more frequent and severe adverse reactions (fever, headaches, malaise)
Rabies	Inactivated virus grown in human diploid cells	Travel to areas for >1 mo where rabies is a constant threat	H—allergy to previous doses P—not contraindicated in high-risk persons; ID route should be completed >30 days before travel; ID route should not be used with concurrent chloroquine or mefloquine administration	~30% have local reactions; ~20% have mild systemic reactions of headache, nausea, aches, and dizziness; rarely neurologic illness; occasional (6%) immune complex reactions with booster doses occurring 2–21 days after vaccination
Typhoid Oral	Live attenuated (Vivotif Berna)	Primary: 1 capsule every other day for 4 doses <sup>§</sup> Booster: same dose every 7 yr	I, P—contraindicated Not recommended <6 yr	Infrequent gastrointestinal upset (nausea, vomiting, diarrhea), rash, mild systemic reactions
Injectable	Vi capsular polysaccharide (Typhim Vi), Acetone and heat-killed <i>Salmonella typhi</i> (10 <sup>9</sup> /mL)	Primary: 1 dose Booster: every 2–3 yr Primary: 2 doses ≥4 wk apart Booster: every 3 yr	Not recommended <2 yr Previous severe local or systemic reaction lasting 1–2 days; acetone-killed vaccines should not be given ID	Frequent local reaction of pain, swelling, and induration; occasional systemic reaction

H, hypersensitivity; I, immunocompromised; ID, intradermal; IM, intramuscularly; P, pregnancy; PO, orally.

\*Immunocompromised persons include immunodeficiency diseases, leukemia, lymphoma, generalized malignancy or acquired immunodeficiency syndrome, or immunosuppression from therapy with corticosteroids, alkylating agents, antimetabolites, or radiation.

†Unofficially required for entry into some countries contrary to World Health Organization recommendations.

\*Ideally, all travelers should be immunized.

§In Canada: 1 sachet every other day for three doses.

Adapted from Hill D: Immunizations. Infect Dis Clin North Am 6:291–312, 1992.

hepatitis B, not only because of unprotected sexual contact with high-risk partners.<sup>43</sup> Even short-term travel has the potential to expose travelers to hepatitis B. A Canadian study showed that approximately 15% of short-term travelers were at risk from blood and body fluid exposure.<sup>44</sup> More important, the risk of hepatitis B from unsterile equipment was highlighted by a WHO study showing that the risk of receiving an injection from unsterile equipment could be as high as 80% in some countries.<sup>45</sup> Furthermore, these data are all the more concerning when the risk for travelers of receiving an injection for illness or injury is substantial. In one study, 8% of U.S. travelers received medical care abroad, of whom 17% received an injection.<sup>46</sup> Currently available recombinant vaccines are highly effective and likely provide lifelong protection.<sup>47</sup> Some experts believe that hepatitis B immunization is appropriate for all international travelers regardless of length of stay and style of travel. Moderate- and high-risk areas for hepatitis B include all of Africa, Asia (except Japan), Greenland, Alaska, and Latin America.<sup>48,49</sup>

Since 97% of international travelers are repeat travelers, providing both hepatitis A and B immunizations for all travelers regardless of their itinerary is a lifetime investment for the travelers. The administration of these two vaccines has been simplified with the introduction of the combined hepatitis A and B vaccine. This vaccine provides excellent protection against both viruses and may be administered in an accelerated schedule that can be completed within 21 days for protection lasting at least 1 year; an additional dose 1 year later is recommended for long-lasting protection.<sup>50</sup>

The risk of typhoid fever has been estimated to be 1 per 30,000 per month of stay in the developing world; however, attack rates have been documented to be 10-fold higher in south Asia (India, Pakistan, and Bangladesh).<sup>51,52</sup> Within these areas, rates are particularly high among VFRs and those traveling off the usual tourist routes. A review of typhoid fever in the United States reported that 77% of all cases occurred among the VFR population.<sup>52</sup>

Typhoid immunization is most frequently recommended for special risk groups. Target groups include all with destinations in south Asia, VFRs, travelers to endemic areas who are likely to eat and drink under poor hygienic conditions (i.e., rural travel), and long-stay travelers.

The most frequently recommended typhoid vaccines are the live attenuated multidose oral vaccine developed from the Ty 21a mutant strain of *Salmonella typhi* and the Vi capsular polysaccharide vaccine administered intramuscularly in a single dose. Both vaccines have been shown to protect 55% to 75% of recipients, depending in part on the degree of exposure to the organism.<sup>53–55</sup> The oral vaccine appears to provide more prolonged protection when four capsules are taken as marketed in North America (4 or 5 years vs. 2 or 3 years), but in Europe, where only three packets are sold, protection is limited to 1 year. This oral vaccine is associated with compliance problems because vaccine administration is undertaken by the recipient.

Although the risk of meningococcal disease has not been quantified, it appears to be greatest among travelers who live among indigenous populations in overcrowded conditions in high-risk areas.<sup>56</sup> The vaccine is recommended for long-stay travelers to the meningitis belt in sub-Saharan Africa (the savanna region extending from Mali east to Ethiopia) or for short-term travelers to this area during the dry season (December to June).

As noted previously, the quadrivalent (A, C, Y, and W-135) vaccination is required for entry to Saudi Arabia by those making the annual Hajj or Umra.

Japanese B encephalitis is a mosquito-borne, viral encephalitis found throughout much of the rural Indian subcontinent and Southeast Asia.<sup>57</sup> The risk of Japanese encephalitis is 1 per 5000 per month of stay in an endemic area. Twenty-four cases of Japanese encephalitis have been reported in travelers over the 15-year period from 1978 through 1992.<sup>58</sup> Although most infections are asymptomatic, among those who develop clinical disease the case fatality rate may be as high as 30%, with severe neurologic sequelae occurring in 50% of survivors.<sup>59</sup> Japanese encephalitis vaccine is highly effective but has been associated with allergic reactions in 1:200 to 1:1000 vaccinees.<sup>60,61</sup> The vaccine should be reserved for those with overnight stays in rural endemic areas for more than 3 weeks.<sup>62</sup>

Few cases of rabies have been reported in travelers, but there are few data on the risk of infection. The incidence of animal bites per 1000 per month of stay ranges from 1.7 to 3.6. The risk may be as high as 2% per year.<sup>63–65</sup> A 3-year study in Nepal showed that the incidence of possible rabies exposures among tourists was 1.9 per 1000 people per year.<sup>66</sup> The incidence of possible exposure to rabies while trekking was 1.2 per 1000 people per year. From 1980 to 1992, five imported cases of rabies in U.S. citizens were reported; in three of these cases, the source of infection was a bite from a pet dog.<sup>67</sup> Risk is highest among children, who may not report bites and who tend to have a greater affinity for small animals. Approximately 40% of bites are in children, of which the majority are on the head and neck.<sup>68,69</sup>

Travelers to the developing world should be counseled on avoidance of animals, particularly dogs, prompt and thorough cleansing of animal bite wounds, and postexposure rabies prophylaxis. Pre-exposure immunization is recommended for prolonged travel (because of cost considerations), for those with an occupational risk of exposure (e.g., veterinarians and spelunkers), and for participants in bicycle tours (magnets for dogs) in areas where rabies is a significant threat.<sup>70,71</sup>

## TUBERCULOSIS

People who will live for prolonged periods in developing countries and those who will have close contact with locals are at increased risk of exposure. It is estimated that for nonmedical travelers the risk of tuberculosis infection is approximately 3% per year.<sup>72</sup> The efficacy of bacilli Calmette–Guérin (BCG) is still debated, although the vaccine is not commercially available in the United States. However, WHO and many European countries recommend BCG for infants younger than 6 months of age, long-term travelers, and health workers traveling to developing countries. Side effects, ranging from draining abscesses at the site of immunization (common) to disseminated infection (rare), must be weighed against the risk of exposure to active tuberculosis for the traveler—a risk that varies directly with the intimacy and duration of contact with the indigenous population. If BCG vaccine is not administered, long-stay travelers (>3 months) should have at least one baseline tuberculin skin test placed before travel and repeated at 1- or 2-year intervals (3 months after exposure) if the risk continues.

## TRAVELERS' DIARRHEA

S. L. Gorbach wrote that “travel expands the mind and loosens the bowels.”<sup>73</sup> Several studies have shown that diarrhea is the most frequent health impairment among travelers to developing countries, affecting one- to two-thirds of all travelers.<sup>74–77</sup> Among those who become ill, 30% will remain in bed and another 40% will have to curtail their activities.<sup>73</sup> In general, countries with higher standards of living present lower risks of travelers' diarrhea.<sup>76–79</sup> Although all age groups are at risk, the incidence is highest among the very young, presumably due to increased fecal-oral contamination<sup>80</sup>; those with decreased gastric acidity<sup>81</sup>; and those in the 15- to 29-year-old age group, probably because of their adventurous lifestyle and ingestion of larger amounts of potentially contaminated foods.<sup>76,82,83</sup> Bacterial pathogens are the most frequent cause of travelers' diarrhea, particularly enterotoxigenic *Escherichia coli* (ETEC), enteroadherent *E. coli* (EAEC), and *Shigella*, *Salmonella*, and *Campylobacter* species<sup>84</sup> (see Table 120-1). However, the prevalence of each organism varies according to season and destination. For example, *Campylobacter* (increasingly fluoroquinolone resistant) is the most frequent cause of travelers' diarrhea in areas of Southeast Asia, notably Thailand, whereas ETEC is the most frequent cause of diarrhea in most other developing destinations.<sup>79</sup> When counseling travelers about diarrhea, several issues must be considered: food and water precautions, chemoprophylaxis, self-treatment of illness, and immunization.<sup>61</sup>

### Food and Water Precautions

Unpeeled fruits, uncooked vegetables, and food that has been cooked or stored at insufficiently hot or cold temperatures, respectively, are believed to be the main sources of enteric pathogens for the traveler. An additional important source is unpurified water and ice cubes made from it. Tap water and ice cubes should be avoided unless there are strong assurances of proper treatment. Organisms in contaminated ice will survive concentrations of alcohol found in drinks mixed with tequila and whisky.<sup>85</sup> Since swallowed water can lead to infection, swimming in water that is contaminated by sewage should also be avoided.<sup>86</sup>

Tea or coffee is safe if consumed hot. Commercially bottled, carbonated beverages are highly recommended since carbonation results in an acid pH that will effectively kill bacteria over a period of several days.<sup>86</sup> Unpasteurized milk and milk products should be avoided.<sup>87</sup> If safe beverages are not available, travelers may need to disinfect water from potentially contaminated sources. Since almost all enteropathogens are readily killed at 100°C, bringing water to a boil is sufficient for disinfection.<sup>88</sup> Tap water “too hot to touch” has not been shown to be reliably disinfected; even in situations in which a low inoculum of organisms may be transmitted, such as in toothbrushing, bottled water is to be preferred.

Although not effective for resistant cysts such as *Cryptosporidium*, chemical disinfection with the halogens iodine or chlorine is an otherwise effective method of water purification. Two drops (0.1 mL) of 5% chlorine bleach or four drops of 2% tincture of iodine should be added to a liter of water and allowed to stand for 30 minutes at room temperature (20°C) before using.<sup>86</sup> Commercial tablets and iodine crystals

serve the same purpose; however, it is important to note that colder water temperature and turbidity will inhibit the purification process, necessitating a longer contact time.<sup>88,89</sup> Various new products containing, for example, chlorine dioxide (Pristine), appear to be more effective and better tolerated than standard halides and, with sufficient contact time, will eradicate *Cryptosporidium* cysts.<sup>90</sup>

Unlike the straightforward approaches to water and beverage precautions, avoidance of contaminated food entails considerably more restrictions. Raw foods are best avoided. Not only should food be well cooked but also it should be served hot. Reheated foods may not be safe because of the presence of preformed heat-stable toxins. Since vegetables are not infrequently grown in “night soil” (human excrement used for fertilizer) or washed with fecally contaminated water before display, they should be well cooked or treated adequately. Only fruit that can be peeled by the traveler should be eaten. Pastries are an excellent source of substrates for bacterial proliferation.

It should be noted that the location where meals are taken is important. Studies from Mexico have shown that the incidence of travelers' diarrhea is higher when food is purchased from street vendors or restaurants or eaten at the homes of locals than when travelers prepare their own meals.<sup>91</sup>

Unfortunately, many studies have shown that education regarding food and water precautions has a decidedly low efficacy in the prevention of travelers' diarrhea. In one study, stricter observance of precautions was associated with a greater likelihood of acquiring diarrhea, explained by a recall bias.<sup>92</sup> In a subsequent prospective study, 98% of international travelers committed dietary indiscretions within 3 days; the incidence of diarrhea was proportional to the number of “mistakes” made.<sup>93</sup> If one considers the standard precautions outlined previously, it is clear that flawless observance may be virtually impossible, particularly among vacationers, who, wanting to relax and indulge in local cuisine, are more likely to be noncompliant with food precautions. For this reason, the concepts of chemoprophylaxis and self-treatment have gained popularity in recent years. One particularly insightful colleague noted, “Boil it, peel it, cook it, or forget it—easy to remember, impossible to do” (Lawrence Green, personal communication, 1995).

### Chemoprophylaxis

Given the high risk of travelers' diarrhea and the difficulty in maintaining food and water precautions, a variety of pharmacologic interventions have been evaluated to prevent this illness. Since bacterial pathogens account for the majority of episodes of travelers' diarrhea,<sup>94–96</sup> antibiotics and bismuth subsalicylate (BSS) have been the focus of testing for its prevention (Table 120-3).

BSS, an insoluble salt of bismuth and salicylic acid, is hydrolyzed in the stomach to bismuth oxychloride and salicylate. The exact mechanism of its action is not completely understood, but it appears to involve both antimicrobial activity linked to the bismuth moiety and antisecretory activity associated with the salicylate portion.<sup>97,98</sup> Studies of BSS have shown a protective effect of up to 65% with the liquid form, 60 mL four times per day (4.2 g/day), or tablet form, two tablets four times per day (2.1 g/day).<sup>99</sup> BSS is generally safe but should be avoided in those with salicylate hypersensitivity or in those

**Table 120-3** Antimicrobial and Nonantimicrobial Prophylaxis of Travelers' Diarrhea

Drug	No.	Dose	Location	Protection (%)
<b>Antibiotics</b>				
TMP-SMX	87	1 DS mg qd	Mexico	71–95
Trimethoprim	145	200 mg qd	Mexico	59
Doxycycline	44	100 mg qd	Mexico	68
Mecillinam	22	200 mg qd	Honduras	76

Lactobacillus GG	160	$2 \times 10^9$ CFU	Morocco	39
<i>Saccharomyces boulardii</i>	350	$6.7 \times 10^9$ CFU	Africa, Asia, Middle East	26

CFU, colony-forming units; DS, double-strength tablet (trimethoprim 160 mg/sulfamethoxazole 800 mg); TMP-SMX, trimethoprim-sulfamethoxazole.

already taking salicylates, anticoagulants, or antihyperuricemic drugs. Also, BSS interferes with absorption of doxycycline, which may be used for malaria, rickettsial, and leptospiral chemoprophylaxis and for treatment. Studies of the use of lactobacilli to prevent travelers' diarrhea have shown minimal or no efficacy.<sup>100–103</sup> The protective efficacy of antibiotics for travelers' diarrhea varies with the season and geographic area visited, which in turn determine the likely pathogens and degree of antibiotic resistance.<sup>104</sup> The widespread use and abuse of antimicrobial agents globally has resulted in the emergence of resistant organisms, particularly enteric pathogens.<sup>79</sup> Previously used antibiotics for the prophylaxis of travelers' diarrhea, such as doxycycline and trimethoprim sulfa, are no longer recommended due to significant bacterial resistance in most areas of the world.

In view of their activity against most bacterial enteropathogens, quinolone antibiotics—notably ciprofloxacin, gatifloxacin, levofloxacin, and ofloxacin—have become the agents of choice for the prevention and treatment of travelers' diarrhea. Protective efficacy has ranged from 88% to 94% in various areas of the world.<sup>105–107</sup> However, reports of quinolone resistance are increasing. In Thailand and Egypt, approximately 90% and 50%, respectively, of *Campylobacter* isolates were resistant to ciprofloxacin but sensitive to azithromycin.<sup>108,109</sup> Quinolone resistance rates among travelers with diarrhea, however, were markedly lower.<sup>84</sup> Although toxicity from quinolones remains low, these agents can cause central nervous system symptoms, which potentially could be aggravated by antimalarials such as chloroquine or mefloquine and may augment xanthine or theophylline toxicity. Also, they are not recommended for children or pregnant women. However, a number of travel medicine and pediatric infectious disease experts use very short-term quinolone regimens for self-treatment in children who develop travelers' diarrhea. Rifaximin, a nonabsorbable antibiotic, was approved by the U.S. Food and Drug Administration (FDA) for use as treatment for bacterial diarrhea.<sup>110,111</sup> Comparative trials have shown that rifaximin is

equally effective as quinolone antibiotics for this use.<sup>112</sup> There is no approved indication for use of this drug for the prophylaxis of travelers' diarrhea, although some consider it useful, especially since a significant number of travelers may suffer from prolonged postinfectious irritable bowel syndrome.<sup>113–115</sup>

The indications for antibiotic prophylaxis of travelers' diarrhea are controversial since it is well established that self-treatment regimens are highly effective in shortening the course of illness.<sup>116,117</sup> Routine use of antibiotic prophylaxis in travelers' diarrhea has not been endorsed by the National Institute of Health Consensus Development Conference,<sup>74</sup> and this view was reiterated at a meeting of travelers' diarrhea experts. Even strong advocates of chemoprophylaxis do not recommend its routine use.<sup>118–121</sup> Prophylaxis with BSS, a quinolone antibiotic, or rifaximin may be considered for less than 3 weeks' duration for the following groups of travelers: those who repeatedly develop diarrhea during their travels, those with diminished protective gastric acidity, those who cannot afford incapacity for even 1 day (e.g., athletes, military personnel, and businesspeople), and those with an underlying medical disorder for whom travelers' diarrhea may be poorly tolerated (e.g., those suffering from inflammatory bowel disease, brittle insulin-dependent diabetes mellitus, chronic renal failure, or AIDS, although the last group should take extra care to avoid such potentially devastating infections as cryptosporidiosis, not prevented by antimicrobial agents). Vaccine development against travelers' diarrhea has focused on preventing ETEC since it is responsible for the majority of cases. Because of the similarity between the cholera toxin and heat-labile toxin of ETEC, efficacy studies of the oral cholera B subunit whole-cell vaccine to prevent travelers' diarrhea have been performed. Field trials showed an overall protective efficacy of 23%, which increased to 52% when ETEC was isolated and to 60% when ETEC was associated with another pathogen. This cross-protection was extremely short-lived, lasting less than 3 months.<sup>122</sup> However, those receiving this cholera vaccine must still use food and water precautions and carry an antibiotic for self-treatment of diarrhea due to other pathogens.

## Self-Treatment

The overriding principle in the management of travelers' diarrhea is the maintenance of an adequate fluid and electrolyte balance. Rehydration can be achieved with tea with sugar, bottled soft drinks, juices, or electrolyte-containing oral rehydration solutions such as those formulated by WHO.<sup>123,124</sup> Because of damage to the intestinal lactase-producing cells by enteric pathogens, dairy products should be avoided during illness.

When dysenteric symptoms are absent, nonantibiotic preparations alone may be useful in the management of travelers' diarrhea. BSS 30 mL every 30 minutes for eight doses reduces diarrhea by 25%.<sup>125</sup> Loperamide up to 16 mg/24 hours reduces the duration of diarrhea by 42%<sup>126</sup> and is more effective than BSS<sup>127</sup> for diarrhea reduction and abdominal pain but less effective for nausea. However, loperamide should be avoided during bouts of dysentery, pragmatically defined as diarrhea with fever and/or blood admixed to the stools, unless used with an antibiotic. Kaolin- and pectin-containing agents are not very effective.<sup>128</sup> Therapy with lactobacilli or other probiotics has not been shown to be effective in modifying the course of travelers' diarrhea.<sup>129</sup>

Few would disagree that most travelers should carry an antimotility agent and an antibiotic for self-treatment of diarrhea that occurs during travel.<sup>130,131</sup> Many studies have shown that antimicrobial therapy leads to symptomatic improvement and a reduction in the duration of illness, particularly in those infected with ETEC and *Shigella*<sup>116,117,132</sup> (Table 120-4). Antimicrobial therapy of nontyphoidal salmonellosis remains controversial because of the potential for antibiotics to prolong convalescent excretion of the organism<sup>133</sup>; however, the duration of illness is decreased with the use of quinolones.<sup>116</sup> A theoretical concern remains that travelers may inadvertently self-treat with antibiotics when they have illness due to *E. coli* O157, but this organism rarely is a cause of travelers' diarrhea.

Quinolones, and in some cases azithromycin, have become the antibiotics of choice for self-treatment. Studies have shown

single-dose therapy and 3- to 5-day courses to be equally effective, except when *Shigella dysenteriae* is the offending pathogen.<sup>117,132,134–137</sup> Loperamide does not appear to enhance the effect of ciprofloxacin.<sup>117,138</sup> A study of U.S. soldiers in Thailand has led to concern about the continued usefulness of quinolone antibiotics for the management of travelers' diarrhea because of *Campylobacter* resistance.<sup>109</sup> Although azithromycin was an efficacious alternative, the drug was less effective than ciprofloxacin against other pathogens. Two different studies in Mexico showed that rifaximin and azithromycin were as effective as ciprofloxacin for treatment of travelers' diarrhea.<sup>112,139</sup> More data are needed to confirm these results in different geographic areas.

## MALARIA

More than 30,000 North American and European travelers develop malaria each year.<sup>140</sup> Studies have shown that the majority of travelers who acquire malaria are VFRs.<sup>141–143</sup> They visit travel clinics infrequently for pretravel health advice and usually do not follow recommendations concerning antimalarial chemoprophylaxis. However, they often visit high-risk malarious areas, particularly sub-Saharan Africa. The risk of malaria per month of stay without prophylaxis is highest in sub-Saharan Africa and Oceania (1:50 to 1:1000) and during the past decade has increased more than fivefold in travelers to Kenya. The risk is intermediate (1:1000 to 1:12,000) in travelers to Haiti and the Indian subcontinent, and it is low (<1:50,000) in travelers to Southeast Asia and to Central and South America.<sup>144</sup> Of the 1200 to 1500 cases of malaria reported annually in the United States, most of those due to *Plasmodium falciparum* occur in travelers returning or immigrating from Africa and Oceania.<sup>145</sup> With the worldwide increase in chloroquine- and multidrug-resistant falciparum malaria, decisions on chemoprophylaxis have become more difficult. In addition, the spread of malaria due to primaquine- and chloroquine-resistant strains of *Plasmodium vivax* has added further complexity to the issue of malaria prevention and treatment.<sup>146,147</sup> Compliance with antimalarial chemoprophylaxis regimens and the use of personal protection measures to prevent mosquito bites are keys to prevention.<sup>141</sup> Several studies indicate that only approximately 50% of travelers adhere to basic recommendations for malaria prevention.<sup>148–150</sup> Travelers must be educated about the risk of malaria, personal protection measures against mosquito bites, appropriate chemoprophylaxis, symptoms of the disease, and measures to be taken in case of suspected malaria during travel. This approach is outlined in the checklist for travelers to malarious areas (Box 120-1). In order to make the previously discussed determinations, travel medicine advisors must conduct a careful review of the itinerary, including whether urban or rural areas will be visited, the length of stay, style of travel, and a medical history, including allergies, previous experience with antimalarials, and the likelihood of pregnancy.

## Personal Protection Measures

*Anopheles* mosquitoes, the vectors of malaria, are exclusively nocturnal in their feeding habits; protection from mosquito bites from dusk to dawn is highly effective in reducing the risk of

**Table 120-4 Treatment of Travelers' Diarrhea**

Drug	Dose	Duration (Days)
Standard dose		
TMP-SMX	1 DS bid	3–5
Norfloxacin	400 mg bid	3–5
Ciprofloxacin	500 mg qd/bid	1–5
Ofloxacin	300 mg bid	3
Levofloxacin	500 mg qd	3
Azithromycin	500 mg qd	3
Bismuth subsalicylate	30 mL q 30 min for 8 doses	
Single dose		
Standard therapy		
TMP-SMX	4 DS	
Norfloxacin	800 mg	
Ciprofloxacin	500 mg–1 g	
Fleroxacin	400 mg	

TMP-SMX (DS, double strength), trimethoprim 160 mg/sulfamethoxazole 800 mg.

**Box 120-1** Checklist for Advising Travelers to Malarious Areas: Key Issues to Be Considered**Risk of Malaria and the Presence of Drug-Resistant *Plasmodium falciparum* in the Area of Destination**

## Antimosquito measures

- Insect repellants
- Knockdown insecticides
- Bed nets
- Long-sleeved shirts, trousers

## Chemoprophylaxis

- Contraindications to use of antimalarials
- Appropriate drug regimen
- Need to start drug before travel, during exposure, and for 4 weeks after leaving the malaria-endemic area
- If necessary, need for self-treatment
- Adverse effects of antimalarials
- Warning that malaria may develop despite chemoprophylaxis
- Warning that fellow travelers or locals may recommend alternative drug regimens that may be less effective

## In case of illness, travelers should be informed about

- Symptoms of malaria (unexplained fever, with or without headache, muscle aches, chills, weakness, vomiting, or diarrhea)
- Need for prompt medical help if malaria is suspected since it may be fatal if treatment is delayed; for diagnosis, a blood sample should be examined on one or more occasions
- Self-treatment in special circumstances, the need to take it only if prompt medical care is not available, and the need to seek medical advice as soon as possible after self-treatment

Adapted from World Health Organization: International Travel and Health. [www.who.int](http://www.who.int).

infection (although *Aedes* mosquitoes carrying dengue fever virus bite during the day). When practical, travelers should wear protective clothing, such as long-sleeved shirts and long pants, when outside during evening hours. The most effective method of preventing mosquito bites is to combine a pesticide such as permethrin on clothing with an insect repellent containing DEET (diethylmetaltoluamide) to exposed skin.<sup>151</sup> Although all concentrations of DEET (from 10% to 99.9%) are equally efficacious in preventing mosquito bites, the duration of action is proportional to the concentration (e.g., 30% DEET lasts 4 to 6 hours, whereas 99% DEET provides 8 to 10 hours of protection). Newer controlled-release formulations with lower concentrations of DEET provide prolonged protection.<sup>152</sup> DEET is well tolerated, but serious adverse reactions such as toxic encephalopathy have rarely occurred in very young children who were exposed to excessive amounts for extended periods.<sup>153–156</sup> The Environmental Protection Agency and the American Academy of Pediatrics have recommended that 30% DEET may be used in children 2 months of age or older.<sup>157</sup> This recommendation is not uniformly accepted by experts in all countries.<sup>158</sup> Also, DEET has been shown to be safe during the second and third trimesters of pregnancy.<sup>159</sup> Insect repellents should be applied sparingly to intact skin and washed off when there is no longer a risk of mosquito bites. Although the cosmetic product Skin-So-Soft has some

repellent activity, it requires frequent (hourly) reapplication.<sup>154,160</sup> Picaridin has been shown to be equally effective as DEET.<sup>161–163</sup>

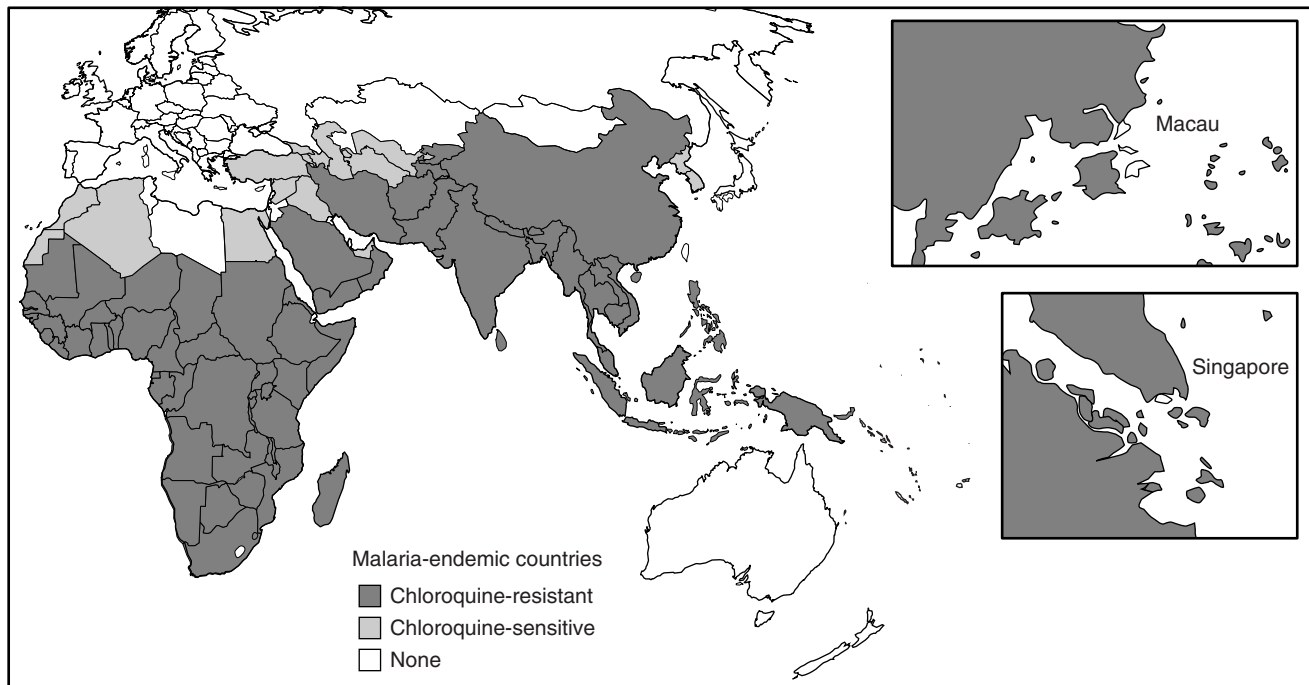

Efficacy rates of up to 80% in the prevention of malaria have been shown by using bed nets impregnated with permethrin.<sup>164,165</sup> A pyrethroid-based flying insect spray should be used to clear the bed net and room of mosquitoes. Where bed nets are not available, mosquito coils and other preparations of vaporized pyrethrum flowers have been shown to reduce mosquito bites.<sup>166</sup> A number of herbal products that have far less efficacy than DEET are sold in stores or on the Internet.

**Chemoprophylaxis**

Personal protective measures greatly reduce but do not eliminate the risk of malaria. Antimalarials are only suppressives, and they act on the hepatic or erythrocytic stage of the parasite, thereby preventing the clinical symptoms of disease but not infection. No drug guarantees protection against malaria. For this reason, travelers must be informed that any febrile illness that occurs during or soon after travel to a malaria-endemic area should be evaluated immediately by a health-care professional for malaria. Since in only one-third of patients in the United States and Canada who died from malaria was the diagnosis considered before death, it is incumbent upon travelers to inform their health-care provider of the risk of malaria and the need to have it ruled out regardless of the malaria prophylactic used.<sup>167,168</sup>

The choice of a drug regimen for chemoprophylaxis will be dependent on the individual's itinerary, length of stay, age, pregnancy status, use of other medications, general medical history (including previous experience with antimalarials), cost, and the estimation of the risk of drug side effects compared with the risk of developing malaria.<sup>169–171</sup> Antimalarials should be started 1 day to 2 weeks prior to entry to a malarious area, during exposure, and for some period of time after departure. Beginning some antimalarials early ensures an adequate blood concentration of the drug and enables travelers to change to alternative drugs should adverse effects occur. The postexposure period of prophylaxis for antimalarials such as chloroquine, mefloquine, and doxycycline is particularly important to enable the antimalarial to eradicate any organisms that are released from the liver into the bloodstream after departure from a malarious area. This may not apply to *P. vivax* and *Plasmodium ovale* infections, which often have dormant hypnozoites in the liver that may be released many months after the onset of infection. With other medications, such as atovaquone/proguanil and primaquine, this postexposure period may be shortened considerably because these drugs act on the hepatic phase.

The development of resistance to antimalarial drugs has seriously hampered the ability to prevent and treat infections.<sup>172</sup> Chloroquine-resistant *P. falciparum* infections have spread throughout the world except in areas of Central America, Haiti, and the Middle East<sup>173</sup> (see maps). Along the Thailand-Cambodia and Thailand-Myanmar borders, *P. falciparum* malaria is resistant to chloroquine and mefloquine.<sup>174,175</sup> Reports from the Indonesian archipelago and Oceania indicate considerable chloroquine-resistant *P. vivax* and *Plasmodium malariae*.<sup>176,177</sup> However, because of chloroquine-resistant *P. falciparum* in these areas, the problem of *P. vivax* resistance does not affect current recommendations for chemoprophylaxis.

## ANTIMALARIAL DRUGS

Table 120-5 lists the drugs, doses, and adverse effects of available drugs for malaria chemoprophylaxis and self-treatment.<sup>178–180</sup>

### Chloroquine

Chloroquine is a 4-aminoquinolone that acts by inhibiting heme polymerase.<sup>181</sup> Although formulated as chloroquine

phosphate in North America, it is used as a sulfate and hydrochloride salt elsewhere. Chloroquine is well tolerated and in appropriate doses may be safely used by young children and pregnant women.<sup>182</sup> Transient nausea or vomiting are seen in a small proportion of individuals and may usually be reduced by taking the drug with food. Occasionally, headaches or blurred vision are reported. Intense pruritus is well documented, almost exclusively in black Africans.<sup>183,184</sup> Although long-term chloroquine use can produce keratic precipitates, irreversible keratopathy does not occur in the

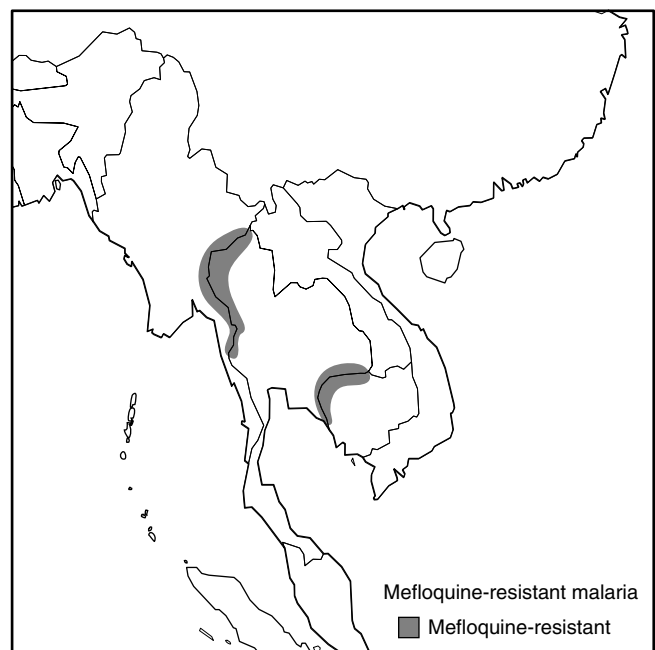

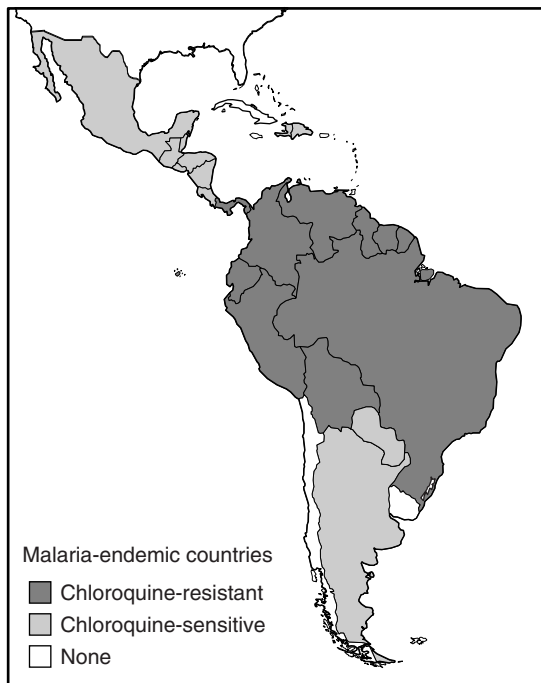

Table 120-5 Antimalarial Drugs for Chemoprophylaxis and Self-Treatment

Drug	Tablet Size	Adult Dose	Pediatric Dose	Side Effects
<b>Prevention</b>				
Atovaquone plus proguanil (Malarone) pediatric tablets	250 mg atovaquone plus 100 mg proguanil	1 tablet daily	11–20 kg: 1 pediatric tablet 21–30 kg: 2 pediatric tablets 31–40 kg: 3 pediatric tablets >40 kg: 4 pediatric tablets	Frequent: GI upset, headache Occasional: fever, rash, cough, insomnia
Chloroquine phosphate (Aralen)	62.5 mg atovaquone plus 25 mg proguanil 150 mg base (250 mg salt) or 300 mg base (500 mg salt)	— 300 mg base (500 mg salt) once weekly	<1 yr: 37.5 mg base 1–3 yr: 75 mg base 4–6 yr: 100 mg base 7–10 yr: 150 mg base 11–16 yr: 225 mg base once weekly 5 mg/kg base	Frequent: pruritis, nausea, headache Occasional: skin eruptions, reversible, corneal opacity, partial alopecia
Hydroxychloroquine sulfate (Plaquenil sulfate) Doxycycline	310 mg base (400 mg salt) 100 mg	310 mg base once weekly 100 mg once daily		See above
Mefloquine (Lariam)	250 mg base	250 mg base once weekly	<8 yr: contraindicated ≥8 yr: 2 mg/kg once daily (maximum 100 mg/day)  <15 kg: ~1/8 tablet 15–19 kg: ~1/4 tablet 20–30 kg: 1/2 tablet 31–45 kg: 3/4 tablet	Frequent: gastrointestinal upset, vaginal candidiasis, photosensitivity Occasional: azotemia in renal disease Rare: allergic reactions, blood dyscrasias Frequent: dizziness, nausea, diarrhea, headache, insomnia, strange dreams Occasional: depression, anxiety, irritability Rare: seizures, psychosis
Primaquine Prevention of <i>Plasmodium vivax</i> relapse	15 mg base	30 mg base/day for 14 days	0.5 mg base/kg/day for 14 days	Occasional: gastrointestinal upset, hemolysis secondary to glucose-6-phosphate dehydrogenase deficiency, methemoglobinemia
<b>Self-treatment</b>				
Mefloquine	15 mg base	30 mg base/day	0.5 mg/kg/day  Same as adults	
Atovaquone plus	250 mg base 250 mg	15 mg/kg in 2 divided doses 12 hr apart (or 1250 mg in 1 dose) 500 mg bid × 3 days		Frequent: gastrointestinal upset, headache Occasional: fever, skin rash, cough
Proguanil (Atovaquone + proguanil = Malarone)	100 mg	200 mg/day × 3 days		Occasional: anorexia, nausea, diarrhea, mouth ulcers Rare: hematuria

doses used for malaria chemoprophylaxis. Chloroquine should be avoided in people with a history of epilepsy.<sup>185</sup> Chloroquine should be stored in childproof containers because as little as a single tablet can be fatal to an infant; overdoses should be reported to a physician immediately.

### Mefloquine

Mefloquine is a 4-quinoline methanol compound that has a prolonged half-life of approximately 30 days<sup>186</sup>; steady-state levels are not reached for approximately 7 weeks, unless a loading dose is used. Comparative studies among travelers have shown that mefloquine is less well tolerated than other anti-malarials, although only 5% of users have to stop the drug due to adverse events.<sup>187,188</sup> A study of malaria chemoprophylaxis in nonimmune travelers to sub-Saharan Africa showed that 40% of mefloquine and chloroquine/proguanil users suffered side effects that were significant enough to interfere with daily activities compared with approximately 30% for doxycycline or atovaquone/proguanil.<sup>187</sup> With mefloquine use, seizures and acute psychosis occur in 1:10,000 to 1:13,000 users.<sup>189–192</sup> Mefloquine is safe during the second half of pregnancy, and there is increasing evidence that it is safe during the first trimester as well.<sup>193–196</sup> However, due to increasing concerns about the neuropsychiatric adverse events, the FDA has required that all health providers distribute drug information with all mefloquine prescriptions.

Mefloquine is currently recommended for all age groups, including infants, at a dose of 5 mg/kg weekly (maximum, 250 mg).<sup>197–199</sup> Mefloquine is contraindicated in those with a history of seizures or psychiatric disorder, including depression or anxiety reaction. The drug should be used cautiously in anyone with a history of such problems. These adverse events tend to occur more frequently among women,<sup>199–201</sup> and they appear to be less common in children.<sup>202</sup> Although mefloquine has traditionally been advised with caution to those who require fine coordination and spatial discrimination, such as airline pilots, mountain climbers, and perhaps divers, there are no data in the literature to substantiate the need for this precaution. The drug should be used with caution in those who have a known cardiac conduction disturbance. It should not be used in those taking chloroquine or quinine-like drugs, including halofantrine.

### Doxycycline

Doxycycline is a tetracycline derivative with a half-life of approximately 16 hours. Its major benefit is that it is effective against multidrug-resistant *P. falciparum* as well as *P. vivax*.

The most common adverse reactions to doxycycline are gastrointestinal disturbances and phototoxicity (exaggerated sunburn).<sup>203,204</sup> The former can be reduced by taking the drug with extra fluids and meals, and the latter can be reduced by using a sunscreen that absorbs ultraviolet (UV) A as well as UVB radiation. It is estimated that 2% to 15% of those using doxycycline will develop phototoxicity. Doxycycline should not be ingested while in the supine position because of the risk of esophageal ulceration caused by lodgment of the tablet in the distal esophagus. BSS (Pepto-Bismol) and antacids decrease doxycycline bioavailability. In addition, vaginal candidiasis is a very common and troublesome problem in female travelers; some advisors suggest carrying fluconazole for self-treatment

as necessary. The drug is contraindicated in pregnant women and children younger than the age of 8 years.

### Proguanil

Proguanil is a dihydrofolate reductase inhibitor that is not commercially available in the United States. In conjunction with chloroquine, it provides suboptimal protection in East Africa and even less in West Africa.<sup>205</sup> The drug has been used as an alternative to chloroquine in chloroquine-sensitive areas of the world. When combined with sulfisoxazole, it was very effective in preventing multidrug-resistant malaria in Thailand.<sup>206,207</sup> Side effects from proguanil include gastrointestinal upset and mouth ulcers, which occur in approximately 35% of users.<sup>208</sup>

### Primaquine

Primaquine is an 8-aminoquinolone that has been shown to be a good second-line alternative for the prevention of all forms of malaria.<sup>209</sup> It has slightly lower protective efficacy against *P. falciparum* compared with the first-line agents (e.g., it has been shown to have 85% to 95% protective efficacy in studies in East Africa, Colombia, and Irian Jaya, Indonesia<sup>205,210–214</sup>). Unlike chloroquine, doxycycline, and mefloquine, primaquine acts on the primary exo-erythrocytic stage in the liver and eradicates dormant hypnozoites. For this reason, the drug may be discontinued soon after leaving the malarious area.

Primaquine may also be used as terminal prophylaxis to prevent relapses of *P. vivax* malaria when taken after departure from a malarious area. It is effective for this indication because it eradicates dormant hypnozoites in the liver. Terminal prophylaxis should be reserved for those who have had prolonged intense exposure outside of sub-Saharan Africa where there is little *P. vivax*, such as missionaries, overseas volunteers, and relief workers.

Primaquine is a potent oxidizing agent that causes hemolysis in people with glucose-6-phosphate dehydrogenase (G6PD) deficiency. The drug has been shown to produce mild (below toxic levels) methemoglobinemia when used for prolonged periods as prophylaxis in those with normal enzyme levels.<sup>213</sup> G6PD levels should be measured before primaquine is used, especially in those who are likely to be at risk for this enzyme deficiency (blacks, southern Europeans, and Asians). Gastrointestinal side effects may be reduced by taking the drug with food. Primaquine is contraindicated during pregnancy.

### Atovaquone/Proguanil (Malarone)

The most recent addition to the armamentarium for the prophylaxis and treatment of malaria is the fixed combination or atovaquone and proguanil (250 mg of atovaquone/100 mg proguanil).<sup>215–217</sup> Atovaquone acts by interfering with the parasite mitochondrial membrane potential at the cytochrome *b-c1* complex.<sup>218</sup> Proguanil is metabolized to cycloguanil, which acts as a folate antagonist, and appears to act by enhancing the collapse of the malarial mitochondrial membrane.<sup>219</sup> Like primaquine, atovaquone/proguanil targets the liver and blood stages, but it does not eradicate the dormant hypnozoites. For this reason, the drug may be discontinued soon after leaving the malarious area. This combination is highly efficacious and is equivalent to mefloquine or doxycycline.<sup>220–223</sup> Adverse events

include headache, gastrointestinal upset, insomnia, dizziness, and rash. Side effects are lowest among current recommended antimalarials; 0.2% to 1.2% of users discontinued the drug compared with 5% for mefloquine and 2% for chloroquine/proguanil.<sup>187,188,224</sup> The high cost of this excellent antimalarial is prohibitive for some users, especially for those visiting friends and relatives and for long-term travelers.

### Recommended Regimens

Table 120-5 lists the recommended antimalarial drug regimens for travelers to malaria-endemic areas. For travel to chloroquine-sensitive areas, chloroquine is the drug of choice. Any of the other first-line drugs may be used as alternatives. However, many travelers prefer atovaquone/proguanil because it may be discontinued soon after departure. For travel to chloroquine-resistant *P. falciparum* areas, atovaquone/proguanil, doxycycline, and mefloquine are the first-line drugs of choice. Primaquine is a second-line drug for these travelers because of the need for a G6PD level prior to its use. For travel to chloroquine- and mefloquine-resistant areas (the Thailand-Cambodia and Thailand-Myanmar borders), atovaquone/proguanil and doxycycline are the drugs of choice. Regardless of the chemoprophylactic regimen recommended, it is important for travel health advisors to indicate to travelers that globally there is no uniformity concerning recommendations for malaria chemoprophylaxis and therefore they are likely to meet fellow travelers and health-care providers overseas who give conflicting advice as to the optimal regimen. Also, in many developing countries, particularly those in Africa, malaria is often overdiagnosed among travelers due to a high rate of false positivity of blood films.<sup>225,226</sup> Travelers should be advised to continue their antimalarial regimen even if they are told they have developed malaria while taking a recommended regimen. Travelers are advised not to purchase antimalarials in developing countries due to high rates of the manufacture and sales of counterfeit drugs.

### Self-Treatment

People who are unable to tolerate effective antimalarials, who are in an area where drug resistance is frequent, or who are unable to obtain medical care in less than 48 hours may consider a self-treatment regimen. In many European countries, malaria chemoprophylaxis is not generally prescribed for travelers to most areas of Asia and Latin America wherever low endemicity prevails; instead, self-treatment regimens are routinely recommended. Unfortunately, however, there is evidence that those who carry self-treatment regimens often use them inappropriately.<sup>227</sup> Also, there is evidence that travelers who use the rapid diagnostic drug kits for malaria do not use them effectively.<sup>228–230</sup>

Few recommend a self-treatment drug in addition to chemoprophylactic medication. Drugs used for self-treatment should be different from the agent used for prophylaxis. Most travel medicine advisors recommend atovaquone/proguanil as the drug of choice for self-treatment. If atovaquone/proguanil is being used for prophylaxis and there is a high degree of suspicion for malaria, mefloquine or the combination of quinine and doxycycline may be used for self-treatment. Although the artemisinin derivatives are not available in North America,

they are the most widely used and effective drugs for the treatment of malaria.

The global spread of drug-resistant malaria has stimulated the search for new approaches to the prevention and treatment of malaria. Several drugs are in the clinical trial stage and are promising alternatives to the current armamentarium. For example, on the horizon is a primaquine analogue, tafenoquine.<sup>231</sup> This drug has a long half-life and is 12 times more potent than primaquine as an antimalarial. A study in semiimmunes showed that three daily doses provided more than 90% protection for more than 3 months.<sup>232,233</sup> However, like primaquine, it is a potent oxidizing agent for which a G6PD level will be required prior to use. Unfortunately, a malaria vaccine for travelers, an ideal preventive strategy, is many years away.<sup>234</sup>

### SEXUALLY TRANSMITTED DISEASES AND BLOOD-BORNE PATHOGENS

During international travel, people often feel a sense of anonymity, may be less sexually inhibited, and may therefore put themselves at greater risk for the acquisition of sexually transmitted diseases (STDs).<sup>235–237</sup> In a survey of 354 British travelers, 4.8% admitted to having casual sex while abroad compared with 6.4% of 484 Swiss travelers.<sup>238</sup> In another study, 5.6% of short-term travelers to Peru had casual sexual contact; only 70% were protected by condoms.<sup>239</sup> A Canadian study revealed that between 5% and 15% engaged in sex with a new partner during travel lasting approximately 1 month.<sup>44</sup> Long-term overseas workers appear to put themselves at even greater risk of acquiring STDs. Among Belgian men working in central Africa, 51% and 31% reported casual sex with local women or prostitutes, respectively.<sup>240</sup> In a study of 2000 Dutch expatriates working in sub-Saharan Africa, 31% of males and 13% of females had casual sexual contacts with African partners; consistent condom use was reported by fewer than 25% of those surveyed.<sup>241</sup>

The most effective ways to avoid STDs during travel are to abstain from sexual activity, have sexual relations with a well-known partner, or use safer sexual practices. These practices will only succeed in preventing infection if applied in each and every sexual encounter, especially when different partners are involved. The highest risk activity is with prostitutes; 90% of prostitutes in Nairobi and more than 50% of those in Bangkok are HIV infected.<sup>242</sup> Since precautions may fail because of condom breakage, having “safe sex” with a high-risk partner may still be dangerous. Some of the STDs that are very common in the developing world include gonorrhea, syphilis, chancroid, chlamydia infection, trichomoniasis, and viral infections such as hepatitis B, C, and HIV-1, HIV-2, and human T-cell lymphotropic virus type I.<sup>236,237,243</sup>

Since several of the pathogens mentioned previously may also be transmitted by exposure to blood and secretions, safer sexual practices are not the only way to avoid infection. People requiring injections overseas (e.g., travelers requiring updating of their immunizations or those with diabetes mellitus) should carry their own needles and syringes, particularly long-stay travelers who plan to visit remote areas. Those who plan to carry medical equipment should be aware that such items may be misconstrued by foreign officials as tools for illegal drug use. A note from a physician indicating why the items are being carried may prevent an uncomfortable or embarrassing situation at a border post. In case of serious

accident or injury, all travelers should know their blood type, particularly if they are traveling with a group, which is considered to be a "safe" source of blood for transfusion. Although no guarantee of safety, blood received from expatriates or staff at embassies, consulates, or international agencies may be less risky with regard to HIV infection. In a study of U.S. travelers to developing countries, it was noted that medical care was sought by 8% of all travelers, of whom 17% received an injection.<sup>46</sup> The significance of this as a risk factor was highlighted by data that showed that in Southeast Asia and in the eastern Mediterranean approximately 80% of injections were given using nonsterile equipment.<sup>45</sup> Furthermore, there appear to be an increasing number of individuals who travel to developing countries for the purpose of having surgical procedures performed. Although the cost is often far less and the availability of donor tissue for transplants is far greater, these procedures are fraught with health hazards. For management of illnesses, surgery, or trauma that is not life threatening, but where blood products may be necessary, transportation to the home country or nearest developed country should be considered in situations in which blood cannot be accurately screened prior to transfusion. Travelers may wish to purchase insurance before departure to cover the enormous cost of being transported home or to specialized medical centers.

### The HIV-Infected Traveler

The HIV-infected traveler is at increased risk of serious infections from a number of pathogens that may be more prevalent at travel destinations than at home. However, the degree of risk depends almost entirely on the state of the immune system at the time of travel. People with AIDS and others with immunodeficiency require special counseling before travel.<sup>244-246</sup>

Several countries continue to deny entry to HIV-positive people, even though there are no data that show that these restrictions decrease rates of transmission of the virus. In general, HIV testing has been required of those people who intend to stay longer than 3 months or who intend to work or study abroad. Some countries accept an HIV serologic test done within 6 months of departure, whereas others require that the test be done at the time of arrival.

Health insurance is highly recommended for HIV-positive travelers. Such policies should include trip cancellation and evacuation insurance in the event of illness.

### Immunizations

In general, live attenuated vaccines are contraindicated for people with immune dysfunction. Exceptions to this rule include measles and yellow fever vaccines for those who must travel to high-risk areas. The HIV-infected person whose CD4 count is less than 200/ $\mu$ L should be discouraged from traveling to areas endemic for yellow fever.

### Gastrointestinal Illness

Travelers' diarrhea is especially problematic in HIV-infected people because of decreased levels of gastric acid and abnormal gastrointestinal mucosal immunity. Salmonellosis, shigellosis, and campylobacteriosis are likely to be more frequent, more severe, and more difficult to treat.<sup>247-249</sup> Both isosporiasis and

cryptosporidiosis are greater risks in developing countries. Because of these potential problems, the HIV-infected traveler must take stringent food and water precautions.

### Other Travel-Related Infections

Reports strongly suggest that HIV infection predisposes to more severe malaria infection, which may stimulate HIV replication.<sup>250,251</sup> There are few data on the interactions between antimalarial drugs and antiretroviral drugs, even though protease inhibitors share common hepatic pathways (e.g., cytochrome P-450). One unpublished study of healthy volunteers suggested that plasma levels of ritonavir decreased with concomitant use of mefloquine. Other vector-borne diseases, such as visceral leishmaniasis and Chagas' disease, may cause serious illness in HIV-infected travelers.<sup>252-254</sup> Precautions to avoid sandfly bites in the case of leishmaniasis and reduviid bug bites in the case of Chagas' disease should be undertaken. Tuberculosis is not usually of concern to the short-term HIV-infected traveler. However, histoplasmosis from caves and coccidioidomycosis in endemic areas are of concern because of their greater morbidity and mortality among HIV-infected people.<sup>255,256</sup>

### Special Health Considerations for Travelers

Issues of chronic illness, disability, pregnancy, and travel with young children are beyond the scope of this article. However, excellent reviews of these subjects have been published.<sup>257,258</sup>

### Mortality

Despite the emphasis on pretravel advice on prevention of infection, deaths from infection are relatively uncommon.<sup>5-9</sup> In a study of 421 deaths among Australian travelers, only 10 (2.4%) were attributed to infection, and in a Scottish study involving 952 people who died abroad, infection occurred in only 34 (3.6%).<sup>8,9</sup> Cardiovascular disease is the most common cause of death in travelers, accounting for 35% to 69% of deaths.

### Motor Vehicle Accidents and Injuries

Trauma is by far the most important preventable cause of death in travelers.<sup>5-9</sup> Injury deaths, particularly from motor vehicle accidents, account for 21% to 26% of deaths that occur during travel. As expected, when those with cardiovascular disease are compared with those who had injuries or accidents, there is a marked preponderance of older people in the former group and younger people in the latter. Motor vehicle accidents can be reduced by advising travelers to avoid travel by road in rural areas at night, overcrowded public vehicles, and riding on motorcycles.

### Bites and Stings

#### Arthropods and Insects

Although malaria is the most important vector-borne infection in travelers, there are others that require attention. Of these, dengue is an increasing problem. The past decade has seen a

dramatic rise globally in dengue, particularly in the Caribbean, Central and South America, and Southeast Asia.<sup>259–261</sup> This has been reflected by a marked increase in travelers.<sup>262</sup> In fact, a study from Sweden reported that 1:3500 travelers to the Malay peninsula become infected.<sup>263</sup> The infection is transmitted by the *Aedes* mosquito, which prefers an urban and often indoor habitat. This mosquito bites during the day, particularly in the hours of the early morning and late afternoon. In addition to insect precautions, some vector-borne diseases can be prevented by prophylactic medication. For example, loaiasis can be prevented by taking 300 mg (adult dose) of diethylcarbamazine once each week while in a very heavily infested area, such as Central or West Africa.<sup>264</sup> Unfortunately, diethylcarbamazine is no longer available in the United States, except from the CDC drug service, which will provide it to clinicians who are treating documented cases. Tick- and mite-borne typhus, relapsing fever, bartonellosis, and plague can be prevented by using doxycycline prophylaxis 100 mg/day during exposure.<sup>265</sup> For the most part, prophylaxis of these infections is not recommended except for a very select group of individuals at high risk. Chagas' disease, transmitted by the night-biting reduviid bug, can be prevented by the use of a bed net and by avoiding sleeping in thatched huts and/or those with mud and stick walls.

Travelers who walk through undergrowth or have close contact with animals are at risk of tick infestation. Tick-transmitted diseases include Lyme disease, ehrlichiosis, relapsing fever, tularemia, typhus, and Congo-Crimean hemorrhagic fever. The risk of a tick bite can be reduced by wearing long sleeves and pants, tucking the latter into socks, and by using effective insect repellents such as DEET. Permethrin clothing spray will protect against tick bites for 2 weeks or more. Finally, a "tick check" of the entire skin should be performed each night by the traveler.

Venomous scorpions are found in many areas of the developing world. Children are at particular risk of dying from a scorpion bite.<sup>266,267</sup> The risk of a scorpion sting can be reduced by shaking out boots, shoes, blankets, sleeping bags, and clothing before use; consistently and properly using a mosquito net; wearing shoes when walking at night; not putting one's hands blindly into ground holes, wood piles, and so on; wearing gloves when cleaning rocks or debris; and removing debris from around housing and camping areas.

### Animal and Snakebites

Although many travelers worry most about bites from snakes and spiders, it is the dog bite that is a much more common and potentially fatal problem. Mouth flora from domestic animals may cause overwhelming infections (e.g., *Pasturella multocida*) in those who are splenectomized. Consideration should be given to providing such travelers with an antibiotic that may be used in the event of a bite. In many countries, a significant proportion of stray dogs carry rabies, a uniformly fatal disease.<sup>64</sup> In addition to receiving preexposure rabies immunization, the more practical approach is to avoid petting or touching animals, particularly dogs, in rabies-endemic areas. Animal bites, licks, or scratches require prompt and careful management.

Snakebites are a major problem among populations forced to live and work, relatively unprotected, within the snake's chosen environment.<sup>268</sup> By avoiding high-risk situations, most travelers can avoid being bitten. Snake charmers should be

observed at a considerable distance. Travelers should be advised not to disturb, corner, or attempt to handle a snake; even a severed head can strike. Walking in undergrowth or deep sand without boots, socks, and long trousers should be avoided. Flashlights should be used at night; unlit paths are particularly dangerous after rainstorms. Other prohibitions include the collection of firewood or movement of logs or boulders with bare hands and putting one's hand or a stick into burrows, holes, or crevices.

### Diseases Transmitted by Soil and Water

Schistosomiasis is a helminthic disease that infects more than 200 million people worldwide in areas of South America, the Caribbean, Africa, the Middle East, and Southeast Asia. To avoid schistosomiasis, travelers should be advised to stay out of freshwater in most developing countries. Swimming in the ocean or freshwater pools without snails is safe. Travelers who cannot control their urge to swim in freshwater should confine themselves to the middle of a lake. After emerging from potentially contaminated water, travelers should dry off quickly in an attempt to prevent skin penetration by the parasite. By allowing infested water to stand for 48 hours, the infectivity of the schistosome larvae in the water will be eliminated. Studies strongly suggest that DEET in a lipid formulation prevents cercarial penetration and therefore may be a practical approach in the prevention of infection when schistosome-infested water cannot be avoided.<sup>269–271</sup>

Leptospirosis is another risk associated with freshwater flooding and ecotourism. Infection can be prevented in unavoidable high-risk situations by taking doxycycline 200 mg per week.<sup>272</sup>

Walking barefoot exposes the traveler to a variety of hazards, including tungiasis (the sand flea), snakebites, cutaneous larva migrans from larvae of the dog and cat hookworm, human hookworm infection, and strongyloidiasis. Sandals provide only partial protection.

### Adaptation to the Environment

Excessive sun exposure can cause erythema and sunburn, chemical hypersensitivity, eye damage, bleaching of skin, and predisposition to skin cancers, including malignant melanoma.<sup>273,274</sup> The effects of UV irradiation can be minimized by the use of sunscreens that either absorb or block harmful UV light. UVB radiation (290- to 320-nm wavelength) is the major cause of sunburn and chronic skin damage, whereas UVA radiation (320 to 400 nm) is the cause of most sensitivity reactions. The efficacy of a sunscreen in the prevention of UVB damage may be determined by the sun protection factor (SPF) assigned to it. The SPF indicates how long one can stay in the sun without burning. Although sunscreens with an SPF 15 offer 93% protection, travelers are advised to use higher SPF values because of the tendency to apply too little, too late.<sup>275–279</sup> Data are conflicting concerning the effect of concomitant use of sunscreens and insect repellents. One study showed a 33% decrease in sun protection,<sup>280</sup> whereas another showed no effect of sunscreen on insect repellent efficacy.<sup>281</sup>

Travelers who are taking drugs such as a tetracycline or sulfonamides, which can cause photosensitivity reactions, should use a sunscreen that contains benzophenones or protects

against UVA as well as UVB. Data show that the incidence of malignant melanoma has increased dramatically from 1 in 1500 in the 1930s to 1 in 90 in 2000.<sup>282</sup> Sun exposure, especially blistering sunburn in childhood, appears to account for the 60-fold increase in incidence of this potentially fatal skin cancer.<sup>283</sup>

## Heat Acclimatization

Although the body possesses the mechanics to survive in extremely hot climates, time is required to put the adaptive mechanisms into play.<sup>284</sup> The adaptation process can take from 1 to several weeks depending on the severity of the climate. Children adapt to hot environments very quickly, whereas unfit, obese people, the elderly, and those with cardiovascular problems are at greatest risk of suffering from disorders associated with a hot climate.<sup>285</sup>

In hot climates, the body's main defense against heat is perspiration. In hot weather and in the absence of strenuous exercise, the average person must replace at least 1.5 L of fluid per day. Cold fluids are best, whereas alcohol and caffeinated drinks are poor choices because they tend to increase fluid excretion. Since sweat contains both water and salt, it is important to replace salt by eating salty foods or adding extra salt to food. Finally, appropriate clothing will help to prevent heat illness. Clothing made of natural fibers, such as cotton and linen, allows air to circulate. Light colors reflect light and are preferable to dark fabrics.

## Jet Lag

Jet lag, the result of a desynchronization of biologic rhythms, is often experienced by travelers who have not had enough time to adjust to a new time zone during a long journey.<sup>286</sup> It affects nearly all travelers crossing more than three time zones. Symptoms of jet lag include fatigue, insomnia, decreased appetite, disequilibrium, a change in bowel habits, and headache. A variety of practical techniques can be used to reduce jet lag. If possible, one should allow 1 day to adjust to every time zone crossed. It is advisable to readjust one's schedule to local time as soon as possible. Naps during the day may be helpful as long as they are kept to less than 45 minutes to avoid the groggy feeling that occurs on awakening. Travelers on a tight schedule are advised to break up a long journey to reduce the adjustment time required at the final destination. Caffeine and alcohol, especially before and during night flights, should be avoided to reduce the risk of sleep disturbance. It has been suggested that alterations in diet can assist in reducing jet lag, although there are no scientific data to support this.<sup>287</sup>

Studies of zeitgebers (light cues that affect body rhythms) have shown that alteration in the amount of daylight exposure will affect the production of melatonin, which can, in turn, assist in adjusting the body's biorhythms.<sup>288,289</sup> The following regimen has been suggested: West-to-east travelers crossing 6 or fewer time zones should increase their morning outdoor light for the first few days after arrival, exposing themselves to at least as many hours of light as the number of time zones crossed. Those crossing 7 or more time zones should stay indoors early in the morning and get their sunlight later in the day. These schedules should be reversed for those traveling from east to west. This method works only when light comes from an

outdoor source, and in general, even if one cannot adhere to the specific recommendations, the greater exposure to the outdoors on arrival appears to be helpful in adjustment. Indoor light can be used to overcome jet lag if the source provides 25,000 lux.<sup>290</sup> Several special lamps are commercially available.

Short-acting mild sedatives have been shown to improve sleep and daytime performance in shift workers.<sup>291</sup> However, prograde amnesia and rebound insomnia may occur.<sup>292</sup> Some consultants recommend zolpidem tartrate (Ambien) instead.<sup>293</sup> A number of studies of airline crews have shown that melatonin has the potential to reduce jet lag.<sup>294–300</sup> It is recommended that for eastbound travelers, melatonin 3 to 5 mg should be taken before departure at 2 or 3 AM destination time for 3 nights prior to departure and at bedtime for 4 days after arrival. Westbound travelers need not take melatonin prior to departure but only after arrival at bedtime for 4 nights. Since melatonin is not FDA approved and its manufacture is not standardized, recommendation of this agent is controversial.

## High-Altitude Sickness

Rapid exposure to altitudes higher than 10,000 ft (3000 m) above sea level can cause a variety of serious medical problems<sup>301–307</sup>: acute mountain sickness (AMS), high-altitude pulmonary edema, high-altitude cerebral edema, and high-altitude retinopathy. The incidence and severity of high-altitude sickness are related to the altitude achieved, speed of ascent, amount of physical exertion, and degree of acclimatization. The most effective way to prevent AMS is to stay at an intermediate altitude (6000 to 8000 ft) for 2 days before gradually ascending to higher elevations. Alcohol and sedatives should be avoided. Acetazolamide (Diamox, a sulfa drug) 125 to 250 mg every 12 hours (or 500 mg of a sustained-release formulation once daily) beginning 1 or 2 days before ascending and continuing at high altitude for 48 hours can prevent or diminish symptoms of AMS in many but not all people.<sup>308–310</sup> Dexamethazone (Decadron) 4 mg every 6 to 12 hours for 48 hours before and after a rapid ascent may also be helpful in preventing the symptoms of AMS.<sup>311,312</sup> Concurrent prophylactic use of both drugs may be more effective than either alone.<sup>313</sup> Nifedipine has been shown to prevent high-altitude pulmonary edema when used prophylactically at a dose of 20 mg of a slow-release preparation taken before ascent in the following way: one dose per day for 2 days, then one dose twice a day for 1 day, followed by three times a day on the day of ascent.<sup>314,315</sup> Ginkgo biloba has not been shown to prevent altitude sickness.<sup>316–318</sup> Zolpidem may be used for insomnia because it does not suppress ventilation at high altitude.

## DEEP VEIN THROMBOSIS AND TRAVEL

The issue of the risk of development of deep vein thrombosis (DVT) during travel, particularly air travel, has been highlighted due to several deaths from pulmonary embolism following long-haul flights (usually more than 5 to 8 hours). Initially, the problem was called "economy class syndrome," although it appears to also occur in those who fly in the more exclusive cabins.<sup>319</sup> A variety of case-control studies have examined the risk of DVT in airline passengers.<sup>320–323</sup> Two of three studies did show a relation between venous thrombosis

**Box 120-2** First-Aid Kit and Travel Medications\***Long-Term and High-Risk Travel**

## First-aid kit

Absorbent cotton  
 Gauze  
 Adhesive tape  
 Alcohol swabs  
 Antiseptic  
 Band-Aids, butterfly closures  
 Moleskin for foot blisters  
 Safety pins, scissors, tweezers (or Swiss army knife)  
 Tensor bandage  
 Disposable syringes (3 to 5 mL) and needles (22 to 25 gauge)  
 Thermometer  
 Petroleum jelly (Vaseline)

## Medications

Analgesic  
 Antihistamines  
 Antinausea/-motion sickness  
 Antidiarrheal (see Travelers' Diarrhea in text)  
 Oral rehydration solution  
 Antimotility agent  
 Antipyretic  
 Antibiotic  
     Systemic, bowel, bladder: ciprofloxacin, ofloxacin, norfloxacin, rifaximin (the latter two are not systemic)  
     Skin, respiratory tract: cephalexin, clarithromycin, azithromycin, levofloxacin  
 Topical: (mupirocin, fusidic acid)  
 Antifungal (topical)  
 Antimalarial  
 Insect repellent  
 Laxative  
 Sunscreen (sun protection factor  $\geq 15$ )  
 Sunburn cream, spray  
 Water purification tablets, cup

**Short-Term and Low-Risk Travel**

## First-aid kit

Band-Aids  
 Moleskin (for foot blisters)  
 Scissors, tweezers (or Swiss army knife), safety pins

## Medications

Analgesic  
 Antidiarrheal  
 Oral rehydration solution  
 Antiperistaltic (loperamide)  
 Antibiotic (ciprofloxacin, ofloxacin, norfloxacin)  
 Antibiotic, topical (mupirocin, fusidic acid)  
 Antihistamine  
 Antimalarial  
 Antinausea/-motion sickness  
 Laxative  
 Insect repellent  
 Sunscreen (sun protection factor  $\geq 15$ )  
 Sunburn cream, spray  
 Water purification

and air travel, but the third study did not.<sup>322</sup> (The latter study was the best designed and lacked referral bias.) Another study examined the incidence of DVT and showed that travelers were significantly more likely to have both a DVT and embolus if they traveled more than 8 hours.<sup>324</sup> A study by Scurr and colleagues in the United Kingdom revealed that 1 in 10 travelers developed symptomless DVT, and the use of below-the-knee compression hose made a significant difference in flights more than 8 hours.<sup>325</sup>

Venous stasis appears to be the common denominator, although other risk factors have been identified, including previous DVT or pulmonary embolus, congestive heart failure, cancer, obesity, age (the elderly), and estrogen therapy, and some believe that dehydration may play a role as well.<sup>326–328</sup> There is a growing consensus on the basis of a variety of studies,<sup>326–328</sup> including a meta-analysis by Adi and associates,<sup>329</sup> that the risk of DVT on prolonged international flights is very low unless additional risk factors are present.<sup>330</sup> Some international carriers have begun showing videos on board that demonstrate in-seat exercises that passengers may perform, presumably to keep blood flowing. In addition, it has been recommended that during long flights travelers should occasionally walk the aisles of the aircraft and flex and extend their calves. Certainly, high-risk individuals should do so. In addition, those at high risk should ask their health-care provider whether they should take low-molecular-weight heparin for travel, or even Coumadin. It is controversial whether antiplatelet drugs, such as aspirin, play a role in prevention. Support hose has been shown to be effective and is recommended for some.<sup>331</sup>

**TRAVELER'S HEALTH KIT**

Healthy travel requires relying on the recommendations made in this article as well as common sense. Carrying a travel health kit (Box 120-2) containing items most commonly required and desired can be very helpful.<sup>332</sup> Furthermore, allowing oneself the time to prepare prior to traveling, as well as time to adjust on arrival, is the key to productive and enjoyable travel.<sup>333–336</sup> In addition, knowing the risks associated with travel and what one can anticipate in the returning traveler who is ill will help the health-care advisor develop an appropriate perspective in provision of the pretravel health advice.<sup>337</sup> Finally, the World Wide Web may be a very useful source of information for the potential traveler and the individual providing health advice.<sup>338,339</sup>

# Migrant, Immigrant, and Refugee Health

SUSAN A. MALONEY  
LUIS S. ORTEGA  
MARTIN S. CETRON

## INTRODUCTION

The global migration landscape has undergone substantial changes in the past quarter century, and the number of population groups contributing to global mobility is steadily rising. The volume of global migrants more than doubled between 1975 and 2000, from 84 million in 1975 to 175 million in 2000. The International Organization for Migration (IOM) estimates that the number of global migrants in 2050 will reach 230 million.<sup>1</sup> Migration is truly a major social phenomenon, with many complex links to economic, trade, social, security, and health policies. In the dynamic relationship between migration and health, immigration has long been recognized

to have a large impact on disease epidemiology and the use of health services in migrant receiving nations<sup>2,3</sup> For example, the impact of immigration on disease epidemiology is demonstrated by the global epidemiology of tuberculosis. Tuberculosis (TB) is a major global cause of infectious disease morbidity and mortality; however, rates of TB in most regions of the developing world are many times higher than those in the developed world (the TB prevalence gap) and are decreasing at a much slower rate.<sup>4</sup> Many migration-receiving countries in the developed world have had stable or increased migration of persons from regions with high TB prevalence, while at the same time having successfully decreased TB incidence in their native-borne population, further exacerbating the prevalence gap. Consequently, the majority of TB cases in migration-receiving countries such as the United States and Canada are now being diagnosed in foreign-born populations from high-prevalence source countries.<sup>5,6</sup> (Fig. 121-1).

Many immigration-receiving countries have prearrival medical examination requirements and protocols for entering migrants, which vary both by the types of populations screened and by the diseases for which examination is required. The health conditions tested through the medical examination procedures required by countries such as Canada, Australia, New Zealand, and the United States are determined on the basis of the risk or danger that these conditions can represent to public health and safety and the additional costs that may be incurred by national public services expenditures.<sup>7-11</sup> In general, these medical examination procedures include a review of the past medical history, a physical examination, and tests that include a chest radiograph and laboratory analyses. The diseases most frequently tested to determine visa eligibility or admissibility of a migrant are infectious diseases such as tuberculosis, sexually transmitted diseases, and mental or behavioral conditions. Immigration regulations

**FIGURE 121-1** Number of tuberculosis cases in U.S.-born vs. foreign-born persons, United States, 1992–2002. (Data from the Division of Tuberculosis Elimination, Centers for Disease Control and Prevention.)

**FIGURE 121-2** Number of foreign-born persons living in the United States, 1900–2000. (Data from the Center for Immigration Studies, Washington, D.C.)

in these countries do allow for the consideration of medical waivers to inadmissible health conditions. Although many immigration-receiving countries in Europe either do not require prearrival health evaluations or have fewer requirements and only limited grounds for refusal of admission based on health grounds, most have provisions for notification and inspection if a communicable or serious health condition is recognized or suspected.<sup>12,13</sup>

### U.S. MIGRATION AND HEALTH SCREENING POLICIES

The number of foreign-born persons living in the United States, approximately 28 million, is greater than ever before in the nation's history<sup>14</sup> (Fig. 121-2). In 2004, the foreign-born proportion of the total U.S. population reached approximately 12%, a proportion comparable to the peak reached during the great immigration wave at the turn of the 20th century. In contrast to the previous 20th century U.S. immigration wave, which was dominated by Eastern Europeans who were driven from their countries of origin by such factors as persecution and poverty (so-called “push factors”), the 21st century immigration wave, which began in the 1970s, is characterized predominantly by Hispanic followed by Asian migrants who are attracted to the United States for economic opportunities (or “pull factors”). In both waves of migration, migrants have brought with them not only skills and cultural traditions that enriched the U.S. economic and social fabric, but also

diseases and disease exposures that were different from those existing in U.S.-receiving communities. In addition, 21st century migrants are more mobile and remain connected to their countries of birth, typically making several back and forth journeys to visit friends and relatives (VFR). New immigrants and refugees, who cross disease prevalence gaps and frequently travel to visit friends and relatives, constitute potentially high-risk populations for translocating communicable diseases of public health significance.

The U.S. Department of Homeland Security has reported that approximately 60,500,000 migrants enter the United States annually (Table 121-1).<sup>15</sup> These migrants include immigrants, refugees, migrants adjusting their visa status, persons with non-immigrant visas, persons in short-term transit status, and other groups that entered the United States without inspection, including undocumented migrants. The majority of these migrants are not required to undergo health screening prior to U.S. entry (see Table 121-1). Given the immense numbers of persons crossing U.S. borders and finite resources for evaluation and surveillance, U.S. migrant health screening policy focuses on migrants planning to establish permanent U.S. residence, since this group has the largest potential long-term impact both on disease epidemiology and health care resource utilization. Currently, the U.S. Immigration and Nationality Act (INA) requires that medical screening examinations be performed overseas for all U.S.-bound immigrants and refugees, and in the United States for migrants applying to adjust their visa status to permanent residence (“green cards”).<sup>10,11,16,17</sup>

**Table 121-1** Categories and Number of Migrants Entering the United States by Medical Screening Requirements, 2002

Category	Annual No.	Medical Screening	Screening Site	Screening Location
Immigrants	384,427	Yes	Panel physicians	Overseas
Refugees	26,839*	Yes	Panel physicians	Overseas
Status adjusters	679,305	Yes	Civil surgeons	United States
Nonimmigrants	27,907,139	No	—	—
Short-term transit	~30,000,000	No	—	—
Others†	~1,500,000	No	—	—
<b>Total</b>	<b>~60,500,000</b>			

\*Numbers are below traditional annual arrivals because of new security requirements following 9/11/2001.

†Others include migrants who entered the United States without inspection, including those who entered with and without proper documentation. Data from U.S. Department of Homeland Security, Washington, D.C.

In 2002, more than 1,000,000 immigrants, refugees, and migrants seeking visa status adjustment underwent medical screening examinations. The remainder of this chapter covers U.S. medical screening issues for immigrants and refugees.

### REQUIRED OVERSEAS MEDICAL SCREENING EXAMINATIONS FOR U.S.-BOUND IMMIGRANTS AND REFUGEES

Over 400,000 immigrants and refugees arrive in the United States annually; immigrants make up approximately 90% of arrivals, and refugees close to 10%.<sup>15</sup> Trends in the number and regions of origin for U.S.-arriving immigrants and refugees are presented in Figures 121-3 and 121-4. From 1997 to 2002, more than 2.4 million immigrants arrived in the United States; the number of arrivals and regions of origin remained relatively stable over the 6 years examined. Between 357,000 and 410,000 immigrants arrived annually: 43% from Asia/Oceania, 26% from the Americas (with the majority [roughly 60%] from Mexico), 13% from the Caribbean, 12% from Europe, and 7% from Africa. From 1997 to 2004 (projected), close to 480,000 refugees arrived in the United States; in contrast to immigrants, the number of arrivals and regions of origins have changed markedly over the 8 years examined. From 1997 through 2001, the number of refugees entering the United States remained stable at approximately 70,000 per year. However, after the September 11th terrorist attacks on the United States, increased security requirements delayed some refugee processing, and therefore the number of refugees arriving in 2002 and 2003 decreased to 30,000 or less. It is projected that between 50,000 and 70,000 refugees will arrive in the United States by the end of 2004. The number

and proportions of arriving refugees from different regions of the world also changed over the 8 years examined. In 1997, the majority (70%) of arriving refugees were from Europe and Central Asia, with only 9% from Africa. In contrast, in 2004, it is projected that more than 35% (approximately 25,000 refugees) will be from Africa. These trends have important implications for medical evaluation and treatment of refugees, both overseas and stateside, since refugees from Africa have relatively high rates of certain diseases, including immunodeficiency virus (HIV) infection, TB, malaria, intestinal helminth infections, and other tropical diseases (e.g., schistosomiasis) and likely lack routine vaccination coverage.

All immigrants and refugees migrating to the United States are required to have a medical screening examination overseas, which are performed by local physicians (panel physicians) appointed by the local U.S. embassy.<sup>10,11</sup> The mandated medical examination focuses primarily on detecting diseases determined to be inadmissible conditions for the purposes of visa eligibility. These diseases include certain serious infectious diseases such as infectious tuberculosis, HIV infection, syphilis and other sexually transmitted infections, and infectious Hansen's disease. Other diseases designated as inadmissible conditions include mental disorders associated with harmful behavior and substance abuse. For the purposes of determining the inadmissibility of an applicant, medical conditions are categorized as class A or B. Class A conditions are defined as those conditions that preclude an immigrant or refugee from entering the United States. Class A conditions require approved waivers for U.S. entry and immediate medical follow-up upon arrival. These conditions include communicable diseases of public health significance, a physical or mental disorder associated with violent or harmful behavior, and drug abuse

**FIGURE 121-3** U.S. immigrant arrivals, 1997–2002. (Data from the U.S. Department of Homeland Security, Washington, D.C.)

**FIGURE 121-4** U.S. refugee arrivals, 1997–2004. (Data from the U.S. Department of Homeland Security, Washington, D.C.)

or addiction. Class B conditions are defined as significant health problems: physical or mental abnormalities, diseases, or disabilities serious in degree or permanent in nature amounting to a substantial departure from normal well-being. Follow-up evaluation soon after U.S. arrival is recommended for migrants with class B conditions. If an immigrant or refugee is found to have an inadmissible condition that may make them ineligible for a visa, a visa may still be issued after the illness has been adequately treated or after a waiver of the visa eligibility has been approved by the U.S. Department of Homeland Security.

In 1996, a new subsection was added to the INA requiring that persons seeking immigrant visas for permanent residency show proof of receipt of at least the first dose of all vaccination series recommended by the American Committee for Immunization Practices (ACIP). Although these regulations apply to all adult immigrants and most immigrant children, internationally adopted children who are younger than 10 years of age have been exempted from the immunization requirements as a consequence of strong objections posed by advocacy groups, who cited safety concerns over immunization practices in several origin countries. Refugees are not required to meet the INA immunization requirements at the time of initial entry into the United States but must show proof of vaccination at the time they apply for permanent U.S. residence, typically within 3 years of U.S. arrival.

The U.S. Centers for Disease Control and Prevention (CDC), Division of Global Migration and Quarantine (DGMQ), is responsible for providing technical guidance to the panel physicians performing the overseas medical screening examination.<sup>16</sup> The testing modalities recommended for the medical

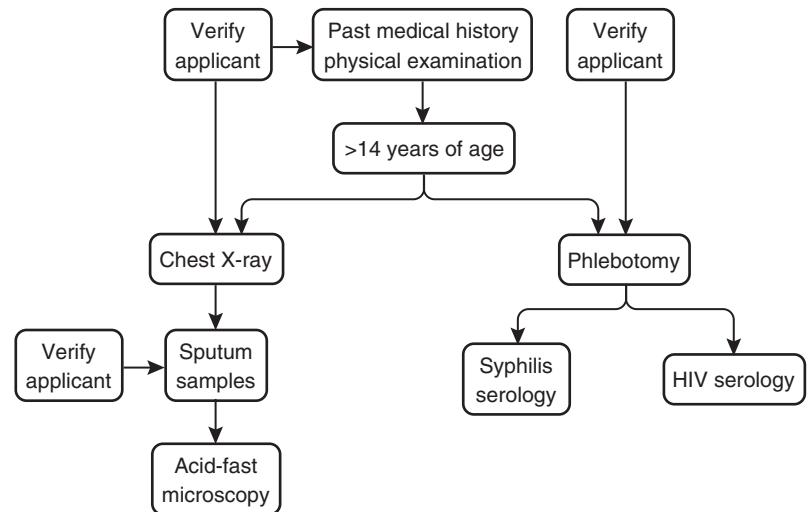

examination are outlined in Table 121-2, and the algorithm for the required overseas medical screening examination is presented in Figure 121-5. The CDC DGMQ is also responsible for monitoring the quality of the overseas medical examination process at more than 650 panel physician sites (health care staff, radiology facilities, and laboratories) worldwide, through its Quality Assurance Program (QAP). Owing to limited resources, not all panel physician sites can be visited and assessed annually. Sites are prioritized for monitoring based on the number of immigrant and refugee visas processed and

country-specific prevalence of such diseases as TB and HIV. In addition, DGMQ performs remediation visits when medical screening examination deficiencies have been identified.

The CDC DGMQ is also responsible for notifying state and local health departments of all arriving refugees and those immigrants with health conditions who are resettling in their jurisdiction and need follow-up evaluation and possible treatment in the United States.<sup>10,11</sup> Under the current system, forms summarizing the results of the overseas medical examination, including classification of health conditions, are manually collected at U.S. ports of entry. This information is transmitted to state and local health departments through the U.S. mail. State and local health departments are asked to report to DGMQ the results of these U.S. follow-up evaluations and also any significant public health conditions occurring among recently arrived immigrants and refugees.

### HEALTH CONDITIONS IDENTIFIED THROUGH REQUIRED OVERSEAS MEDICAL SCREENING EXAMINATIONS

The number and types of health conditions identified through required overseas medical screening examinations among the approximately 2 million immigrants and 280,000 refugees who arrived in the United States from 1999 through 2003 are summarized in Table 121-3. For both refugees and immigrants, the most frequent conditions identified were suspected active and inactive tuberculosis.

The underlying objective of the overseas TB screening process is to limit the entry of persons seeking long-term U.S. residence who have infectious (defined as acid-fast bacilli [AFB] smear-positive) active TB and who therefore pose an immediate public health risk, and to refer others with suspected active and inactive TB for further evaluation and treatment in the United States, where diagnostic facilities and mycobacterial culture capability are generally more readily available and treatment can more easily be monitored and supervised. Suspected active TB (classes A and B1) was identified in 0.96% of immigrants and 0.77% of refugees examined overseas from 1999 through 2003. Previous studies have

reported that during U.S. follow-up, pulmonary TB disease was diagnosed in 3.3% to 14.0% of immigrants and refugees classified overseas as having suspected active TB.<sup>18-24</sup> If these estimates are used to calculate expected rates of active TB among newly arrived U.S. immigrants and refugees with suspected active TB, the expected rates of pulmonary TB disease for immigrants would be between 29 and 134 per 100,000 persons and for refugees between 23 and 208 per 100,000 persons. These rates are as high and likely higher than the reported TB rate among all foreign-born persons in the United States in 2002 (23.6 per 100,000).<sup>5</sup> Furthermore, compared with the U.S. native-born TB rates (2.8 per 100,000), these expected rates are higher by several orders of magnitude.<sup>5</sup>

These data underscore the importance of assuring timely and appropriate U.S. follow-up evaluation of immigrants and refugees with suspected active TB, since the yield for TB case

**Table 121-3** Number of Health Conditions Identified Through Overseas Medical Screening Examination Among Immigrants and Refugees, 1999–2003

Health Conditions	Immigrants	Refugees	Total
Infectious (AFB+) active TB: class A	29	7	36
Not infectious (AFB-) active TB: class B1	19,206	2140	21,346
Not active TB: class B2	17,026	8025	25,051
HIV	102	735	837
Syphilis	209	62	271
Hansen's disease	13	4	17
Mental disorder associated with harmful behavior	39	18	57
Drug abuse or addiction	5	1	6
<b>Total</b>	<b>36,629</b>	<b>10,992</b>	<b>47,621</b>

Data from Division of Global Migration and Quarantine, Centers for Disease Control and Prevention.

finding is high. Although rates of follow-up for immigrants and refugees identified overseas as class B1 or B2 are relatively high (63% to 99%),<sup>18</sup> problems exist with late or lost arrival notifications in up to 30% of notifications (CDC, unpublished data, 2002). These deficiencies in the current manual notification process can delay the evaluation and treatment of TB cases among immigrants and refugees after arrival in the United States and can potentially contribute to increased TB morbidity and mortality and disease transmission. A CDC initiative to develop an electronic disease notification system for arriving refugees and immigrants is under way to address these deficiencies and is discussed in the following sections.

The number of HIV infections identified during the overseas medical screening examination is relatively small. Early identification of HIV infections among immigrants and refugees is important to assure appropriate notification and linkages to medical services in resettlement communities. Current regulations require that syphilis infections be treated before departure to the United States. During 1999–2003, less than 300 immigrants and refugees infected with syphilis were identified overseas. In reference to other inadmissible conditions listed in Table 121-3, fewer than 20 cases of Hansen's disease, fewer than 60 cases of mental disorder associated with harmful behavior, and only six cases of drug abuse or addiction were identified among U.S.-bound immigrants and refugees.

## **NEW HEALTH SCREENING PROGRAM INITIATIVES TO IMPROVE IMMIGRANT AND REFUGEE HEALTH**

### **Electronic Disease Notification System**

DGMQ has recently embarked on a long-term, multiyear initiative to develop a comprehensive electronic disease notification system to communicate with both national and international partners about diseases and disease outbreaks occurring among mobile populations entering the United States. Such mobile populations include immigrants, refugees, migrants, and international travelers (including temporary visitors). The system, called the Electronic Disease Notification (EDN) system, will integrate data from multiple sources and surveillance systems and will include modules dedicated to specific populations and disease entities of public health importance such as tuberculosis. The EDN-Tuberculosis (EDN-TB) module was prioritized for implementation because of the crucial role it can play in enhancing tuberculosis control and prevention efforts among arriving immigrants and refugees, and it is currently being tested in several U.S. states. The objectives of the EDN-TB module are to (1) use the CDC secure data network to electronically notify health departments of newly arriving immigrants and refugees with class A and class B tuberculosis, (2) provide an electronic system for health departments to inform other health departments of secondary migration of immigrants and refugees with TB conditions within the United States, (3) provide health departments with an electronic system to record and evaluate the outcome of domestic follow-up examinations (4) provide federal and state public health officials with data to evaluate the effectiveness of follow-up of immigrants and refugees with suspect tuberculosis, and (5) allow comparison of overseas health

assessments with domestic follow-up outcomes as part of a comprehensive quality assessment program for overseas TB screening examinations.

### **Enhanced Refugee Health Program Initiative**

It has long been recognized that immigrants and refugees may carry significant disease burdens, which are determined by geographic origin, ethnicity, and living and health conditions in countries of origin or departure.<sup>25</sup> These migrants can suffer from a multitude of health conditions, including infectious diseases (such as tuberculosis and many tropical and parasitic diseases), malnutrition, reproductive health needs, and mental health disorders, often caused by tenuous circumstances in their countries of origin or departure.<sup>25–31</sup> Such disease burdens can seriously hamper migrants' ability to successfully integrate and optimally contribute to their resettlement communities and may cause strain on health and social services systems in the United States.<sup>28</sup> Most of these health conditions are not addressed during the required overseas medical examination process. Refugees do receive state-side evaluation and treatment, usually conducted at state or local health departments, within 3 months of U.S. arrival, but currently there is no standardized nationwide protocol for postarrival health assessment, and therefore the content of postarrival refugee health evaluations varies from state to state, and funding sources are often noted to be inadequate to provide comprehensive services. Further, both refugees and immigrants often have other daily demands to achieve integration into their new living environment that may compete with their need for health evaluations and treatment. Optimizing migrant health prior to resettlement and addressing migrant health needs early in the migration process can be cost-effective and prevent larger expenditures later.<sup>23,32–35</sup> Realization of this fact has led to the development of the U.S. Enhanced Refugee Health Program (ERHP), an initiative aimed at achieving integration of the health needs of migrant populations with facilities of the host and receiving countries. The CDC developed the initiative, in collaboration with the U.S. Bureau of Population and Migration (PRM), the International Organization for Migration (IOM), and U.S. state and local health departments, to begin to comprehensively address health care needs of U.S.-destined refugees while they are still overseas, and to facilitate and promote appropriate stateside evaluation and treatment. The ERHP currently focuses on refugees for a number of reasons: (1) refugees are vulnerable populations, exposed to a variety of harsh environmental conditions and diverse diseases, with limited access to health care; (2) a unique opportunity exists to address refugee health concerns during required overseas health assessments; (3) the language and charge of the U.S. Refugee Act provide more latitude to address conditions of public health concern among refugees (in addition to inadmissible conditions); and (4) lessons learned from a focus on the smaller number of refugees may be potentially applicable to the larger numbers of immigrants or other migrant groups.

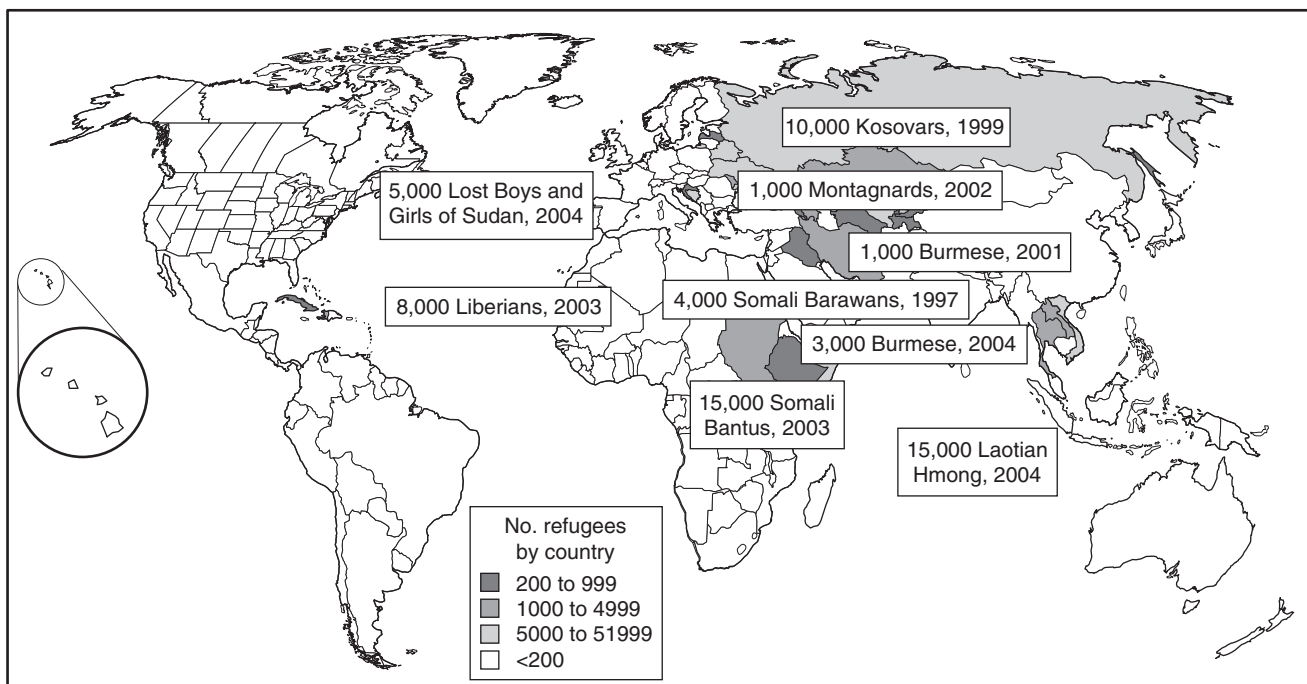

The ERHP strategy is to utilize the required overseas medical examination process as a unique opportunity to assess and improve the health status of refugees overseas, and to incorporate both required screening components for inadmissible conditions and additional expanded components, which

are tailored to specific refugee population needs and targeted to diseases of public health importance. The program first ensures quality staffing and infrastructure in the field, evaluating, training, and lending resources to support the capacity currently in place when necessary. Extending health services in the country of origin or transit allows patients to be served by health-care providers who are closer geographically and often culturally to the patients' circumstances and health needs. Furthermore, through the development of enhanced and electronic data exchange systems, ERHP promotes more timely transmission of population-based health and medical examination data acquired overseas to U.S. health departments in resettlement communities, facilitating appropriate follow-up and treatment of refugees after arrival in the United States. In the future, ERHP will strive to support and standardize follow-up evaluation and treatment of refugees after U.S. arrival by state and local health departments and other community health-care providers.

Since 1997, the CDC has undertaken enhanced refugee health programs for at least eight large-scale, emergent movements of refugee populations and one U.S.-based intervention for the Lost Boys and Girls of Sudan (Fig. 121-6). These programs have included components to provide presumptive predeparture treatment for malaria, intestinal parasites, and other tropical diseases, expanded TB diagnosis and treatment, HIV services, appropriate immunizations, dental and mental health assessments, chronic disease evaluations, and postarrival treatment for schistosomiasis and strongyloides infection (Table 121-4). These programs have successfully prevented thousands of cases of intestinal parasitosis, malaria, and vaccine-preventable diseases and hundreds of cases of TB and other communicable diseases among U.S.-bound refugees.<sup>36-40</sup> Other integral components of the ERHP initiative have been

efforts to provide linkages to U.S. programs in host countries, such as the Global AIDS Program (GAP), which can provide diagnostic, treatment, and prevention services to refugees awaiting U.S. resettlement. Such efforts are aimed at assuring refugees access to needed health-care services in a prompt manner even while still in asylum countries prior to U.S. resettlement, and to reduce the burden placed on host country resources, since overseas interventions can decrease refugee health utilization once in the United States, reduce treatment costs, and avoid overburdening the domestic health system. Finally, some more recent ERHP programs have included enhanced surveillance and response for emerging infectious diseases, including vector-borne and vaccine-preventable diseases, and most recently, H5N1 avian influenza in Asia. As part of the ERHP for Liberian refugees in Côte d'Ivoire, field staff were able to identify Onong n'yong fever, an emerging infectious disease in West Africa, and prevent its importation.<sup>40</sup>

Vaccine-preventable diseases are a source of significant morbidity and mortality in developing countries, and refugees are known to be undervaccinated owing to collapsing public health infrastructure in countries of origin or departure and lack of access to health care.<sup>41</sup> In addition, outbreaks of measles, rubella, and varicella among U.S.-bound Liberian refugees in Côte d'Ivoire and varicella among the Somali Barawans in Kenya in 1997, Somali Bantu refugees in Kenya in 2003 and 2004, and Hmong refugees in Thailand in 2004 were identified and controlled during ERHP programs (unpublished data, CDC).<sup>42</sup> As a result of these and other disease outbreaks, the movement of refugees has frequently been significantly delayed and necessitated substantial additional per capita investments in the resettlement process (e.g., last-minute cancellation of nonrefundable commercial airline tickets and the need for dedicated refugee charter flights), not to mention

**FIGURE 121-6** Enhanced refugee health programs from the Centers for Disease Control and Prevention.

**Table 121-5** Requirements for Routine Vaccination of Immigrants Examined Overseas

Vaccine	Age						
	Birth–1 Mo	2–11 Mo	12 Mo–4 Yr	5–6 Yr	7–17 Yr	18–64 Yr	65 Yr or Older
DTP/DTaP; may include DT	No		Yes			No	
Td		No				Yes	
Polio: IPV or OPV	No		Yes				No
MMR	No			Yes, if born after 1956			No
Hib	No	Yes				No	
Hepatitis B		Yes, through 19 years of age					No
Varicella	No				Yes		
Pneumococcal	No	Yes, through 23 months of age (for PCV)			No		Yes (for PPV)
Influenza			No				Yes, 50 years or older (annually, each flu season)

DT, pediatric formulation diphtheria and tetanus toxoids; DTaP, diphtheria and tetanus toxoids and acellular pertussis vaccine; DTP, diphtheria and tetanus toxoids and pertussis vaccine; IPV, inactivated polio vaccine (killed); MMR, combined measles, mumps; OPV, oral polio vaccine (live); PPV, pneumococcal polysaccharide vaccine; Td, adult formulation tetanus and diphtheria toxoids.

Data from Division of Global Migration and Quarantine, Centers for Disease Control and Prevention.

the obvious risks to refugee health and the threat of importation and spread of disease in receiving communities. To prevent morbidity, mortality, and the threats of disease importation along with the avoidance of costly delays in refugee resettlement, CDC DGMQ recommends that refugees also receive age-appropriate immunizations listed in the *Technical Instructions to Panel Physicians for Vaccination Requirements* (for immigrants) if the vaccines are available in-country or easily obtained (Table 121-5). CDC recognizes that some vaccines may not be available in all host countries, and therefore vaccination with some vaccines may not be feasible. However, common vaccines that can be routinely obtained overseas for use in most host countries include diphtheria and tetanus toxoids and pertussis (DPT), tetanus and diphtheria toxoids (Td), live oral poliovirus (OPV), measles-mumps-rubella (MMR), hepatitis B, and varicella; an initial dose of vaccines in these series should be administered as early as possible before migration to maximize utility and protection. The following vaccinations may not be easily obtained in host countries: *Haemophilus influenzae* (Hib), streptococcus pneumoniae, and influenza. If vaccines are not available in host countries, they should be administered as soon as possible after resettlement in the United States.

Special concerns for internationally adopted children include hepatitis B and C, syphilis, HIV infection, TB, and intestinal parasitic infections, which may warrant screening in addition to a review and update of routine childhood immunizations.<sup>43</sup>

## FUTURE DIRECTIONS

The Enhanced Refugee Health program aims to shift the migration health paradigm away from a focus merely on inadmissible conditions and regulatory exclusion toward integration of migration and health needs, which is advantageous not only for the health of refugee populations but also for those in host countries and receiving resettlement communities. Such an inclusive approach can lead to improved health status and is cost effective for all populations concerned.<sup>35–39</sup> While further refinements to the ERHP strategy are needed, this should be viewed as a dynamic and iterative process rather than a static one. Future directions for achieving more integrated and comprehensive migration health programs and policies include the following:

1. Continuing efforts to tailor migration health policies to incorporate the unique needs of migrant populations and to provide flexibility to address emerging global health issues
2. Expanding the role of migration health assessments in protecting public health of migrants and of receiving and host countries. Priority areas should include the following:
  - a. Support for delivery of essential preventive and treatment interventions, such as vaccinations and treatment for malaria and other parasitic diseases
  - b. Creation of effective surveillance systems for emerging infectious diseases

- c. Development of emergency response capacity
- d. Inclusion of components to address emerging infectious diseases, reproductive and mental health needs, and other diseases of public health importance
3. Applying new information technology to secure electronic information exchange among numerous international and interagency partners and assuring real-time communication of health data along the migration pathway
4. Identifying sustainable funding to support migration health programs, in both receiving and host countries
5. Promoting public-private partnerships to address migrant health issues
6. Developing international and interagency partnerships to facilitate harmonization of policies and integration of global migration and health issues

Ultimately, health and migration are intimately linked and interdependent. Early investment in addressing and integrating the health needs of migrants and of receiving and host communities will facilitate the migration process, improve migrant health, decrease associated morbidity and mortality, avoid long-term health resource and social costs, and protect global public health.

# Infectious Diseases in Modern Military Forces\*

BONNIE L. SMOAK  
ALAN J. MAGILL  
TRUEMAN W. SHARP

## INTRODUCTION

Since the end of the Cold War, military forces from many countries serve outside their homelands in peacekeeping operations and wars. In 2004, over 500,000 U.S. military personnel were operating in 144 countries. During May 2004, United Nations peacekeeping forces were involved in sixteen operations around the world. This included over 55,000 military personnel and civilian police from 97 countries. These individuals may be exposed to diseases not endemic in their home countries and may be at even higher risk for acquiring these diseases than other travelers because of their unique living conditions. While training or deployed, military units living in crowded conditions may have increased rates of transmission of pathogens spread by droplets or aerosol, such as *Neisseria meningitidis* or *Streptococcus pneumoniae*, and poor hygienic conditions in the field may increase the likelihood of diseases transmitted by the fecal-oral route.

Provision of health care to these troops varies by country of origin. Some countries, like the United States, have an extensive military medical system; however, ill reserve soldiers, and even active duty soldiers on leave, may be first evaluated by civilian physicians. Other countries refer all ill soldiers to civilian care. Thus, knowledge of the diseases observed in military populations is needed by all providers and the medical history should always include the question: "Have you ever served in the military?" This chapter describes infectious diseases reported in military populations during the past fifteen years and will help health-care providers broaden their differential diagnoses of the ill soldier or veteran. We use the term *soldier* for brevity's sake to represent all those serving in the armed services, including airmen, sailors, and marines.

## DISEASES TRANSMITTED BY DROPLET OR AEROSOL

Deployed troops and military trainees living in crowded conditions are at increased risk of acquiring diseases transmitted by the respiratory route. Of special concern to the U.S. Armed Forces are respiratory illnesses caused by adenoviruses, influenza, *Streptococcus pneumoniae*, *Streptococcus pyogenes*, and *Mycoplasma pneumoniae*.<sup>1</sup> In the 1950s and 1960s, adenoviruses caused more than 90% of the hospitalized pneumonia cases at training sites during the winter months.<sup>1</sup> To control these outbreaks, the Department of Defense developed and, in 1971, began the routine use of an oral live vaccine in trainees for adenoviral serotypes 4 and 7, the predominant strains observed in military epidemics. Unfortunately, the sole manufacturer of the vaccine ceased production in 1996 and by 1999 respiratory illness rates among trainees increased to levels observed during the prevaccine era.<sup>2</sup> Approximately 10% to 12% of all recruits became ill with adenovirus infections.<sup>2</sup> In 2000, the first deaths since 1972 associated with adenovirus infection occurred in basic trainees.<sup>2</sup> Deaths have continued to occur through 2004 while the U.S. military struggles to re-initiate a vaccine program.

Frequent outbreaks of influenza-like illnesses are reported among U.S. forces even though a mandatory influenza vaccination program occurs each fall. Most outbreaks are the consequences of a lack of vaccination rather than failure of the vaccine and occur when vaccination centers fail to obtain or administer the vaccine in a timely manner.<sup>3</sup> Other outbreaks occur when an influenza strain not contained in the vaccine causes infections.<sup>4</sup> Some outbreaks are due to other respiratory viruses, such as parainfluenza.<sup>5</sup>

Mass chemoprophylactic regimens and vaccination have been required to control *S. pneumoniae* and *S. pyogenes* infections in U.S. training forces. Large outbreaks of pneumococcal pneumonia and group A streptococcal pneumonia occurred among Marine recruits in 2000 and 2002, respectively.<sup>6,7</sup> An outbreak of pneumococcal pneumonia occurred among U.S. Army Ranger students undergoing intense training in the winter of 1998–1999.<sup>8</sup> Interestingly in the aftermath of earlier outbreaks of pneumococcal pneumonia and streptococcal pharyngitis, students had been receiving two doses of benzathine penicillin (4 weeks apart) as prophylaxis at the start of their training since 1991. This practice was discontinued in March 1998, just prior to the outbreak.

There is always concern that troops may be at increased risk of acquiring tuberculosis when they are deployed to countries with high prevalence of this disease. This potential risk has been difficult to verify. Sailors and marines appear to be at higher risk of infection because of their close living and working quarters.<sup>9,10</sup> In 1998, a U.S. Marine on an amphibious ship became ill with a dry cough of one month duration.<sup>11</sup> He was treated for atypical pneumonia twice and stayed onboard the ship for three months before he was transported to a local naval hospital where active tuberculosis was diagnosed. Contact investigation involving 3338 persons identified 712 new latent tuberculosis infections and 21 persons who developed active tuberculosis.

Crowded conditions in military populations facilitate the transmission of other respiratory-transmitted diseases, such as meningococcal disease, measles, chickenpox, and rubella.

\*The views expressed are those of the authors and should not be construed to represent the positions of the Department of the Army, Department of the Navy, or Department of Defense.

Recruits are at especially high risk for meningococcal disease with its high case-fatality rate and potential sequelae that include limb loss, neurologic disabilities, and hearing loss.<sup>12</sup> The emergence of sulfonamide-resistant strains in the early 1960s caused U.S. military researchers to accelerate development of meningococcal vaccines. Since 1971, vaccines have been effective in preventing disease caused by vaccine-homologous serogroups in U.S. recruits.<sup>12</sup> Similar reductions were seen in French, British, and Israeli recruits after the introduction of vaccination programs in the 1990s.<sup>13–15</sup> Sporadic cases and occasional outbreaks still occur. The public health management of these events is made difficult by the number of close contacts of cases and the mobility of a military population. Large numbers of persons may have had close contact with the case because of crowded living and working conditions. In 1995, 340 persons received prophylactic treatment after the sudden death of a soldier on maneuvers from Group B meningococcemia.<sup>16</sup> In 2003, 99 sailors were identified as having close contact with a suspected case of meningococcal meningitis on a U.S. aircraft carrier and received antibiotic prophylaxis.<sup>17</sup> British public health authorities were notified after the patient reported a history of intimate contact during a port visit.

Herd immunity to vaccine preventable diseases, such as measles, varicella, and rubella, is more difficult to achieve in military units because of greater transmission potential from close living and working conditions. In 1995, 120 German paratroopers traveled to Fort Bragg, North Carolina, prior to participating in a joint training exercise at Fort Polk, Louisiana.<sup>18</sup> One evening, three German soldiers developed a maculopapular rash and systemic complaints consistent with rubella infection. The next day the entire contingent was quarantined in their barracks and three more cases occurred during the following week. Serological testing indicated that 10 soldiers in the units were nonimmune, giving an attack rate of 60%. Later it was verified that rubella cases were occurring at their home station in Germany. An outbreak of rubella was also reported on a German ship in 1996, resulting in 20 cases and an attack rate of 57%.<sup>19</sup>

In countries where vaccination strategies to control these diseases in the military have been implemented, the reported incidence of these diseases has greatly decreased. In 1998, the Italian armed services instituted mandatory MMR vaccination for all recruits.<sup>20</sup> The incidence of measles dropped from 1357 per 100,000 recruits in 1997 to 37 cases per 100,000 recruits in 1999. Similar decreases were observed in the incidence of rubella.

## DISEASES TRANSMITTED BY ARTHROPODS

Malaria continues to cause significant morbidity and mortality in military populations serving around the world (see Chapter 90). Deployments to Africa are frequently associated with malaria cases. During a 6-month period in 1995–1996, Brazilian troops deployed to Angola had an 18% attack rate and three soldiers died of cerebral malaria.<sup>21</sup> French troops had malaria rates of 35.7 cases per 1000 person-months during their first month of deployment to the Ivory Coast in 2002.<sup>22</sup> During 2003, a U.S. military unit operating in Liberia had an attack rate of 44%. In each of these incidents, failure to comply with the recommended chemoprophylaxis regimen and the

infrequent use of personal protection measures was responsible for high disease rates.<sup>21,22</sup>

During 1992–1993, over 2000 Dutch marines served as part of the United Nations Transitional Authority in Cambodia.<sup>23</sup> Weekly mefloquine was used and a total of 64 cases of malaria (42 *P. falciparum*, 22 *P. vivax*) were diagnosed in 59 marines, both during and after the deployment. Attack rates differed at various campsites, with one site in a dense forest having the highest at 16.6% (6.4/1000 person-week) compared to 1.0% (0.5/1000 person-week) at all the other sites combined. Compliance with the chemoprophylactic regimen was judged to be good by self-reporting and the testing of serum concentration of mefloquine and its metabolite. Malaria parasites isolated from four Dutch patients and four of seven Khmer patients from the forest campsite were mefloquine-resistant by in vitro susceptibility testing.

Foreign troops serving in Afghanistan are at high risk of acquiring malaria. Over 7000 cases of *P. vivax* infections were reported between 1981 and 1989 in Russian troops demobilized after serving in Afghanistan.<sup>24</sup> Forty-five percent ( $n = 38$ ) of the malaria cases reported in the U.S. Army during 2003 were considered acquired principally in Afghanistan.

In 1993, vivax malaria re-emerged as a threat to military forces and the civilian population in the Republic of Korea. Over 9000 cases were diagnosed in Korean soldiers and veterans from 1993 to 2000.<sup>25</sup> During this same time period, 186 cases were reported in U.S. soldiers who had served in Korea.<sup>26,27</sup> Many of these cases were diagnosed at locations outside of Korea because of the long latency of this temperate strain (>6 months) and the short duty assignment (one year) of the soldiers.

Relapsing malaria caused by *P. vivax* is a recurring problem in deployed forces when they return home. Forty-eight cases of malaria occurred among U.S. forces in Somalia during 1993; most caused by *P. falciparum*.<sup>28</sup> Several hundred cases of malaria from *P. vivax* infections occurred after they returned home.<sup>29,30</sup> A similar pattern was observed in Italian forces serving in Somalia during this same time period. Among 11,624 soldiers, 18 cases occurred in Somalia, while 147 cases occurred after returning to Italy.<sup>31</sup> The scenario was repeated in 1999, when 11,000 United Nations peacekeepers from 17 countries were sent to East Timor to restore order. During the initial 5 months, the Australian Defense Force deployed 5500 soldiers. Sixty-four cases of malaria occurred in-country, with two-thirds of these infections caused by *P. falciparum*. After returning to Australia, 212 malaria cases, almost all due to *P. vivax*, were treated.<sup>32</sup>

The preceding examples illustrate that malaria is a common problem for troops deployed to endemic areas, even when preventive measures were recommended and in some cases enforced. There are many problems inherent in providing effective protection against malaria to immunologically naïve populations, such as soldiers. First, knowledge about the risk of acquiring malaria is frequently incomplete. The geographic distribution of malaria is increasing secondary to population movements, environmental changes, and decreased control efforts. Areas that had once eradicated malaria now are seeing the re-emergence of this disease. Determining if re-emergence has occurred before military forces deploy to an area is difficult because generally public health efforts have ceased in

these areas. Even in areas of established malaria transmission, evaluating the risk can be difficult because rates of transmission can be very focal within a country and the exact movement of the military unit is not known.

The preceding examples also demonstrate the difficulties in determining when primaquine should be recommended as a terminal prophylactic drug regimen for vivax malaria. As noted previously, predicting the risk of infection is difficult. The use of endemic population rates may underestimate the risk because troops may operate in more remote areas and local populations may self-treat and not present to medical facilities. Using rates observed in troops during the deployment also underestimates the risk when military forces are using an appropriate chemoprophylactic regimen. There were few vivax cases during deployments to Somalia and East Timor, but hundreds of cases after the troops returned to their homelands.

As seen in U.S. troops returning from Somalia, even when primaquine is recommended, the effectiveness of the regimen may be low.<sup>29</sup> Noncompliance with the standard drug regimen—15 mg (base) daily for 14-day (15 mg  $\times$  14 days)—is common and commanders rarely require that it be taken under direct observation. Further, some tropical vivax strains require a higher dose than the 15 mg  $\times$  14-day regimen to eradicate the liver stages.<sup>33,34</sup> It is not always known at the time of a policy recommendation if a higher dose regimen should be recommended for a given locale.<sup>30</sup> Given the difficulties in assessing the risk of infection and the generally low effectiveness of the standard 14-day regimen, some military planners decide not to recommend a terminal prophylactic regimen with primaquine. The Dutch did not use primaquine for antirelapse prophylaxis when their troops returned home from Cambodia and estimated that they would have had to presumptively treat a hundred soldiers for each vivax case that did occur.<sup>23</sup>

Improving the effectiveness of primaquine terminal prophylactic regimens is critical to reducing the incidence of vivax malaria in returning military forces. The 15 mg  $\times$  14-day regimen was introduced over 50 years ago during the Korean War. Its success in preventing relapses was because the drug was given daily under direct observation on the transport ships returning troops back to the United States and the temperate strain in Korea was known to be sensitive to this regimen.<sup>35,36</sup> Unfortunately, directly observed therapy is not frequently used today. Later studies suggest that it is the total dose that is important in eliminating the vivax hypnozoites from the liver, not the duration of treatment.<sup>37,38</sup> The selection of the 15 mg  $\times$  14-day regimen was based on safety considerations and was shown to be efficacious in preventing Korean vivax relapses when combined with chloroquine.<sup>33,36,39,40</sup> Alternate regimens that would improve compliance, such as higher daily doses over a shorter time, need to be clinically tested.

The total dose or dose per kilogram of body weight may also have to be changed. The daily 15-mg dose was based on experimental data that showed it was safe to administer it to African-American males with the glucose 6-phosphate deficiency A phenotype without medical supervision and it was efficacious against the Korean strain. Now, many newly described strains around the world are reported to require a higher dose to prevent relapses. A higher dose may also be

needed because soldiers today are heavier than their counterparts from 40 years ago.<sup>41</sup>

In summary, despite having efficacious chemoprophylactic drugs, personal protective measures, and vector control strategies that would protect the majority of military personnel from disease, malaria continues to cause illness and sometimes death among foreign troops deployed to endemic areas. *P. vivax* is the predominant species causing illness in military forces when appropriate chemoprophylaxis is used during the deployment and occurs most frequently in soldiers after return to their home country. It has been extremely difficult to prevent vivax infection in troops after they return home. Health-care providers should always consider malaria in the differential diagnosis of any febrile soldier who has served in a malarious area, especially within the past year.

Dengue infections in troops should be expected when they deploy to dengue-endemic areas (see Chapter 72). During the multinational deployments to Haiti from 1994–1997, dengue was a major cause of febrile illness. When U.S. forces first entered Haiti in 1994, dengue was identified in 29% of the hospitalized febrile patients during the first six weeks of the deployment.<sup>42</sup> The use of vector control and personal protection measures should have reduced this rate, but later in 1995 the attack rate was unchanged. Of 249 hospitalized febrile patients, 32% were infected with dengue.<sup>43</sup> Personal protection measures were not fully utilized.

Dengue infections have occurred in military forces around the world. Cases were identified among U.S. forces in Somalia<sup>44</sup> and Italian troops in East Timor.<sup>45</sup> Epidemic transmission occurred in French troops stationed in French Polynesia in 1989, with an attack rate of 47%.<sup>46</sup> The importation of dengue virus back by soldiers returning from duty abroad is a possibility. Nine Australian soldiers returning from duty in East Timor following peacekeeping operations in 2000 were found viremic in the home station in north Queensland. Fortunately no civilian cases were reported in the area for the following 4 months.<sup>47</sup>

Other arboviruses have been reported in soldiers. French researchers isolated Rift Valley fever virus from the sera of two febrile French soldiers in Chad, 2001.<sup>48</sup> Five U.S. soldiers and one Australian were diagnosed with Ross River virus disease (“epidemic polyarthritides”) during a joint exercise held in Queensland, Australia, during 1997.<sup>49</sup> In 1991, three U.S. Marines stationed on Okinawa developed encephalitis. Laboratory testing confirmed infection with Japanese encephalitis virus. None of the cases had been vaccinated because the vaccine had not yet been licensed in the United States. In summary, military personnel are at risk of being infected with endemic circulating arboviruses when they are deployed overseas. Given the short incubation period of most of these diseases (less than 2 weeks), most ill soldiers and veterans presenting to civilian physicians will have recently returned from their deployment.

Tickborne diseases occur in troops deployed or training in rural areas at home or abroad (see Chapters 50–53). Rocky Mountain spotted fever and human ehrlichiosis have been reported in military forces after field training in endemic areas of the United States. A cluster of tickborne infections at two U.S. military installations led researchers at the Walter Reed Army Institute of Research and the Centers for Disease Control and Prevention to conduct a prospective study that resulted

in the isolation of *Ehrlichia chaffeensis*, the causative agent of human monocytic ehrlichiosis in 1990.<sup>50</sup> A prospective serological study of 1194 U.S. military personnel following a training exercise in Arkansas indicated a 2.5% seroconversion rate to spotted fever group rickettsia (SFGR) and a 1.3% seroconversion rate to *Ehrlichia* species, although most infections were not associated with symptoms (73% of SFGR seroconvertors and 67% of the *Ehrlichia* species seroconvertors did not report symptoms).<sup>51</sup> The use of permethrin-treated uniforms is thought to decrease the risk of tick-borne infections; however, only 35% of the soldiers reported using this preventive measure.

These rates of infection have importance beyond the health of the individual soldier. In 1997, 10 U.S. National Guard members in Iowa presented with symptoms consistent with tickborne diseases shortly after a two-week training exercise in Arkansas.<sup>52</sup> Several of these soldiers, along with others in their unit, had donated blood shortly before becoming ill. Among the 377 blood donors, 12 individuals were found to have confirmed or probable infection with Rocky Mountain spotted fever or ehrlichiosis. Sixty (16%) donors had evidence of asymptomatic seroconversion. A total of 320 units of platelets or packed red blood cells were transfused into 129 recipients in nine states. Seven hundred units were recalled. Ten recipients received units from ill soldiers, although none became ill.

Sporadic cases of SFGR and *Ehrlichia* species infections have been reported in troops deployed abroad. In 2000, a U.S. soldier who had been living in Korea for 3 months presented with fever, rash, leucopenia, and thrombocytopenia. Acute serum obtained on admission demonstrated the presence of IgM antibody to *Ehrlichia chaffeensis*.<sup>53</sup> A U.S. soldier returning from duty in Somalia in 1993 was diagnosed with Mediterranean spotted fever caused by *R. conorii*.<sup>54</sup>

Tickborne disease can affect the operational readiness of an entire unit. In 1992, a large outbreak of African tick bite fever occurred in an U.S. airborne unit that had deployed to Botswana for 2 weeks.<sup>55</sup> Eighteen percent (31/169 soldiers) were clinically ill and had lab confirmation consistent with *Rickettsia africae* infection. Personal protection measures were not fully utilized.

Scrub typhus is an important disease entity to rural and military populations throughout Southeast Asia, Korea, and Japan. Since 1934, outbreaks have been described among U.S. and Japanese troops training in a camp near Mt. Fuji, Japan. Recent outbreaks among U.S. forces were reported in 1995, 2000, and 2001.<sup>56</sup> Attack rates of 1% were observed in each incident. Scrub typhus was once common in north Queensland, Australia, but cases had not been reported for 30 years until 1996.<sup>57</sup> At that time, a soldier was diagnosed with scrub typhus and an investigation followed. Seventeen additional cases were identified. One year later, another outbreak involving 11 cases occurred at the same training site. Based on seroconversion rates, Thai soldiers working near the Thai-Cambodian border during 1992 had an estimated 2.66% annual infection rate.<sup>58</sup>

Infections caused by the protozoan parasite *Leishmania* (see Chapter 94) can cause significant morbidity to military forces worldwide. Numerous outbreaks of cutaneous leishmaniasis (CL) have been associated with military units deployed to jungle training centers. The incubation period of CL varies widely from a few days to many years, but the majority of lesions appear within the first few months after exposure. For short-term training missions, most cases occur after

re-deployment to their home base. Training related outbreaks have occurred in Belize,<sup>59</sup> French Guiana, the Brazilian Amazon,<sup>60-62</sup> and at the U.S. Army-operated Jungle Operations Training Center (JOTC) in Panama.<sup>63</sup> Attack rates (AR) can be surprisingly high in nonimmune soldiers with 80% to 90% reported from French Guiana.<sup>64</sup> A striking example is a report from 1990 of 17 cases of CL seen in 27 Canadian paratroopers (63% AR) on the ground for 6 hours in British Guyana.<sup>65</sup> CL is a serious morale problem for Latin American military organizations. Overall infection rates of 1% to 2%, with much higher epidemic outbreaks in small units are not uncommon in units stationed in remote areas to counter antigovernment insurgencies or narco-trafficking.

CL caused by *L. major* was described in soldiers with Middle East peacekeeping duty associated while serving in the Multinational Force and Observers (MFO) in the Sinai desert.<sup>66,67</sup> Both Israeli and Jordanian soldiers have suffered epidemic outbreaks of CL caused by *L. major* while assigned to duties near the Jordan River valley and the Negev desert.<sup>68,69</sup>

Prior to the deployment of troops to Iraq and Afghanistan for Operation Iraqi Freedom (OIF) and Operation Enduring Freedom (OEF), the U.S. military experience with CL was predominately related to training missions in Central America, especially Panama.<sup>70-72</sup> The recent deployment to Iraq has resulted in the largest outbreak of CL in U.S. forces since WWII.<sup>73-75</sup> Over 700 cases of CL caused by *L. major* have been described to date. The majority of cases were acquired in Iraq with a few cases of CL caused by *L. tropica* acquired in Afghanistan.

Recent military experience with visceral leishmaniasis (VL) is more limited, most likely due to the fact that military operations have not occurred in areas of the world at highest risk for VL, such as the Ganges River drainage in India, Nepal, and Bangladesh, and the southern Sudan. In addition, clinically apparent disease is much less common than inapparent infection in otherwise healthy, nonimmune adults. Sporadic cases of VL have been described in Chad,<sup>76</sup> and in four U.S. soldiers, two cases acquired in Iraq and two in Afghanistan.<sup>73,77,78</sup> VL may present differently in healthy nonimmune adults with lower parasite burdens, making parasitological diagnosis more difficult, and more atypical symptoms.<sup>79</sup> For example, 12 cases of systemic illness caused by *L. tropica*, a parasite usually associated with CL, were described in U.S. soldiers following the first Gulf War in 1991.<sup>80,81</sup> None of these patients presented with typical signs and symptoms of VL and instead presented with fatigue, malaise, gastrointestinal symptoms, adenopathy, transient hepatosplenomegaly, and mild laboratory abnormalities. The syndrome was called "viscerotropic" because parasites were isolated from bone marrow, liver tissue, or lymph nodes.

There are large groups of American military personnel and their families who live in *Leishmania* endemic areas of the world. The U.S. Navy has a naval air station in Sigonella, Sicily. This is an area long known to be endemic for a zoonotic cycle of *L. infantum*, canine reservoirs, and local sand fly vectors. Occasional cases of infantile kala-azar are seen in children of assigned military personnel. Infection rates in humans are not known, but a study in companion pet dogs showed a 75% subclinical infection rate.<sup>82</sup> This much higher than expected infection rate in companion dogs would indicate subclinical human infection occurs, perhaps at much higher rates than expected.

Prevention of *Leishmania* infection in military populations relies on vector personal protection measures (PPMs). The use of permethrin-impregnated uniforms is recommended, but clinical trial data to support such use is limited. Four of 143 (3%) Colombian soldiers wearing impregnated uniforms acquired CL, while 18 of 143 (18%) wearing control uniforms acquired CL.<sup>83</sup> The success in Colombia was not seen in a clinical trial in Iran.<sup>84</sup> Practical insect avoidance measures, combined with treated bed nets and DEET based repellants, can achieve high protection against biting arthropods.<sup>84</sup>

## DISEASES TRANSMITTED BY THE FECAL-ORAL ROUTE

Diarrheal diseases continue to be an important cause of illness in modern military forces. Rates and etiologies reflect regional and seasonal distributions of enteric pathogens. During a training exercise in southern China in 1997, medical officials reported a diarrheal attack rate of 7.3% among 2636 members of the People's Liberation Army during a 20-day observation period.<sup>85</sup> Enterotoxigenic *Escherichia coli* was the predominant pathogen isolated (35%). *Shigella* species were the major bacterial pathogen (40%) among Peruvian soldiers training in the Amazon River basin in 2002.<sup>86</sup> *Campylobacter* infections were a leading cause of diarrhea in U.S. troops training in Thailand during the 1990s as quinolone-resistant strains became more prevalent in that area.<sup>87</sup>

Port visits have been linked to shipboard outbreaks. Twenty-one percent of surveyed U.S. naval personnel ( $n = 500$ ) reported having acute diarrhea during or shortly after departing Alexandria, Egypt, in 1988.<sup>88</sup> An outbreak of cryptosporidiosis occurred on a U.S. Coast Guard cutter that had filled its tank with city water while docked at Milwaukee, Wisconsin, in March, 1993.<sup>89</sup> A massive outbreak was later reported among city inhabitants.<sup>90</sup>

During conflict or a time of rapid buildup of forces, toilet facilities can be primitive consisting of open trenches or wooden latrines. Fly control may not be established and adequate levels of personal hygiene and sanitation are difficult to maintain. These factors, together with crowded living conditions, increase the transmission potential of pathogens transmitted by the fecal-oral route.

In 1990 during the initial months of Operation Desert Shield, outbreaks of watery diarrhea occurred in U.S. troops.<sup>91</sup> This was followed by outbreaks of more severe, bloody diarrhea in the second month. More than 50% of 2022 U.S. combatants surveyed reported at least one episode of diarrhea and 20% of affected combatants reported that it interfered with their work and resulted in a medical visit.<sup>91</sup> In a separate survey, microbiologic studies showed that half of the diarrhea in combatants seeking medical care was of bacterial origins, mostly enterotoxigenic *E. coli* and *Shigella* species.<sup>91</sup> Susceptibility testing showed many multidrug resistant strains reflecting the patterns observed among the endemic population. Empiric antibiotic treatment regimens were altered in response to these resistance patterns. Many of the outbreaks were attributed to ingestion of raw vegetables, especially lettuce, that were procured from countries outside the United States.

Diarrhea control measures among U.S. forces were strongly enforced during Operation Restore Hope in Somalia, 1992–1993. A comprehensive medical surveillance system

that included over 85% of all deployed forces was instituted and found that less than 1% of the force each week sought care for diarrhea during the first 2 months.<sup>44</sup> No large diarrhea outbreaks were observed. *Shigella* species (33%) and enterotoxigenic *E. coli* (16%) were the predominant bacterial pathogens isolated.

An early report about self-reported disease prevalence during Operation Iraqi Freedom and Operation Enduring Freedom (Afghanistan) indicated that diarrhea rates may have been high during the initial phase of deployment.<sup>92</sup> Seventy percent of 2389 volunteers reported at least one episode of diarrhea and 56% reported multiple episodes. Seventeen percent of those with diarrhea reported being on bed rest for a median of 2 days.

Diarrhea rates during deployments on humanitarian missions can be high. British ( $n = 36$ ) and Australian ( $n = 75$ ) medical teams working among the Kurdish refugees in 1991 had different rates of diarrhea during the first 5 weeks in northern Iraq.<sup>93</sup> Diarrhea rates were higher among the British force (69%), which did not use doxycycline for malaria prophylaxis and did not enforce hand- and plate-washing procedures, than the Australian group (36%) who did. In 1994 among a 131-person Dutch military unit serving in the refugee camps in Goma, Zaire, 20% reported diarrhea during the first 3 weeks.<sup>94</sup> On the day of departure, 102 servicemen ate at a local hotel and 59% developed diarrhea shortly after returning home.

Diarrhea continues to be an important disease affecting operational readiness in the military despite having preventive measures which can minimize attack rates. Vaccine development for major bacterial causes of diarrhea in troops is a major area of research for the military.

Norovirus outbreaks are being increasingly recognized among military forces. While outbreaks among civilian ships have received publicity, at least 60% to 80% of cases occur on land.<sup>95</sup> Outbreaks of vomiting were reported in Operation Desert Shield/Storm among American forces and an attack rate of 4% to 9% occurred over a 5-month period in one Marine unit.<sup>96</sup> Ninety-nine soldiers in an Army trainee unit (12%) were hospitalized during an outbreak at El Paso, Texas, in 1998.<sup>97</sup> In May 2002, eleven British soldiers were air-evacuated from Afghanistan when the initial patients presented with a severe acute illness characterized by headache, neck stiffness, photophobia, obtundation, and gastrointestinal symptoms.<sup>98</sup> Two patients required ventilatory support and one patient's illness progressed to disseminated intravascular coagulation. Norovirus infection was later confirmed by laboratory analyses in England.

Explosive outbreaks have occurred on U.S. Navy vessels with several hundred sailors becoming ill in a short time period.<sup>99</sup> For the deployed forces, this infection causes a major diagnostic dilemma. Currently, there are no rapid diagnostic field tests to identify norovirus infection from an unknown chemical or biological attack that produces similar clinical symptoms and attack rates.

## ZOONOTIC DISEASES

Thousands of cases of Q fever (see Chapter 54) have been reported in military units throughout history. An outbreak of Q fever occurred among British and Czech soldiers deployed as part of the United Nations Stabilization Force

in Bosnia-Herzegovina during May and June, 1997.<sup>100</sup> Approximately 4% (26/610 personnel) became infected and over half exhibited clinical symptoms. A flu-like illness was the predominant presentation and three soldiers had atypical pneumonias. A sheep farm was located 100 meters from one of the bases. It was thought that exposure occurred when infectious aerosols were generated during lambing season by the approach and landing of helicopters.

A few cases of Q fever have also been identified in U.S. forces during the recent past. In Operation Desert Storm/Shield, one case of Q fever–related meningoencephalitis, one case of pneumonia, and three individuals who were epidemiologically linked to the pneumonia case and seroconverted were identified.<sup>101</sup> During 2003 in Operation Iraqi Freedom, eight soldiers with pneumonia were diagnosed by serology retrospectively.<sup>102</sup>

It is likely that the incidence of Q fever among soldiers is severely underestimated. Most infections present as a flu-like illness and are self-limited. The most common clinical presentation is pneumonia and is commonly misdiagnosed as a community-acquired pneumonia. Even if primary health-care providers suspected Q fever, confirmation is difficult and requires specimens be sent to a reference laboratory.

Hemorrhagic fever with renal syndrome (HFRS), a rodent-borne disease (see Chapter 68), has caused significant casualties during military conflicts. The war in the Balkans during the 1990s was no exception. In Bosnia, more than 300 military and civilian cases were treated in a single hospital during a 1-year period.<sup>103</sup> In 1995, large outbreaks of HFRS occurred at several sites in Croatia. Of the 129 reported cases, 120 were Croatian Army soldiers. Two of the soldiers died.<sup>104</sup> Severe clinical manifestations were reported in many patients. These infections were caused by a newly described hantavirus, Dobrava, rather than the Puumala virus, which also circulates in this area but causes a milder illness.

The association of rodent-borne diseases and war comes as no surprise. Improperly stored food and garbage in military camps can contribute to an increase in the size of rodent populations. However, military outbreaks have also occurred during field training when the rodent's natural habitat is disturbed. In January 1990, U.S. troops camping in southern Germany during training maneuvers had 16 cases of HFRS for an attack rate in one unit of 8.5%.<sup>105</sup>

In Korea, HFRS affects both civilian and military populations. From 1980 to 1985, over 3000 cases were diagnosed.<sup>106</sup> Approximately 24% of these cases were Korean soldiers, but only 22 cases occurred among American soldiers. An outbreak occurred in 1986 among 3754 U.S. Marines who had participated in a 5-week joint training exercise with Korean troops.<sup>107</sup> Fourteen cases occurred; two died. Of note, eight of the cases became symptomatic after leaving Korea. Infection can occur without exposure to a field setting. Recently, a case occurred in a soldier in which it appeared that the infection was acquired on base in an urban environment.<sup>108</sup>

Leptospirosis (see Chapter 46) is an occupational hazard for soldiers operating in swampy environments. In the early 1980s, some U.S. military units training in Panama had attack rates of 2% to 8%. In response, military researchers tested and demonstrated the efficacy of weekly doxycycline for chemoprophylaxis.<sup>109</sup> In 1987, two clusters of cases occurred in U.S. military personnel serving in Okinawa, Japan, with attack

rates of 47% and 18%.<sup>110</sup> In 1999, 193 Peruvian military recruits trained for 2 weeks in the high jungles near Pichanaqui, Peru.<sup>111</sup> During the subsequent 4 weeks, 78 recruits became ill with an acute undifferentiated febrile illness. Laboratory testing was negative for dengue, Oropuche, Venezuela equine encephalitis, Mayaro, yellow fever, group C bunyaviruses, rickettsia, ehrlichia, and malaria; however, 92% of the cases were positive for leptospirosis by microscopic agglutination test. Like Q fever, this disease is probably under-reported because physicians are unfamiliar with its clinical presentation and difficulty in obtaining laboratory confirmation.

## DISEASES TRANSMITTED THROUGH EXPOSURE TO SOIL AND DUST

Military forces working or training in areas endemic to mycoses that can be transmitted through inhalation are at particular risk of acquiring these infections. Certain field activities that produce dust, such as the driving of vehicles, digging ditches, or cleaning of abandoned buildings, increase the risk for exposure. For American forces, there are at least 10 major military bases located in the southwest desert of the United States where coccidioidomycosis (see Chapter 80) is endemic.<sup>112</sup> Sporadic cases, as well as outbreaks of this disease, occur in military populations.<sup>112–116</sup> From 1981 to 1994, 113 U.S. sailors and Marines were hospitalized in Navy medical facilities for coccidioidomycosis, with primary pulmonary disease representing the most common form (72%).<sup>115</sup> Failure to obtain an adequate travel history and unfamiliarity with this disease has led to delayed or missed diagnoses.<sup>113,116</sup> In 1992, a 27-man Marine reserve unit from Tennessee trained for 3 weeks at Vandenberg Air Force Base, California.<sup>116</sup> A week after returning, one of the reservist developed symptoms of pneumonia and, despite treatment with tetracycline and amoxicillin, his illness persisted. Later during his hospitalization, coccidioidomycosis was diagnosed. Other members of the group (26%) had symptoms consistent with coccidioidomycosis infection. All had sought medical intervention, but only two were diagnosed correctly. Misdiagnoses are not infrequent. During the fall of 2001, elite Navy Special Forces personnel ( $n = 23$ ) trained for 6 weeks in Coalinga, California.<sup>113</sup> Six presented to a local medical clinic during the exercise with cough, fever, chills, night sweats, and malaise, but were diagnosed with a “viral illness”.<sup>113</sup> Because of persistent symptoms, one Navy Seal was evaluated at a military hospital 6 weeks later and a diagnosis of coccidioidomycosis was made. An investigation of the group found that 45% of the team had serologic evidence of acute coccidioidomycosis and all were symptomatic. In summary, physicians attending to any ill military personnel must be vigilant for this disease. Large numbers of personnel train in desert warfare at Fort Irwin, California, and may present with their illness thousands of miles away from this endemic area. Early detection and treatment can prevent progression to disseminated disease and complications.

Melioidosis (see Chapter 34) is an important infectious disease for military personnel because of its multiple modes of transmission, the severity of illness, latent infections that become clinically apparent years after initial exposure, its intrinsic resistance to many antibiotics, and its high relapse rate.<sup>117</sup>

It is a bacterial disease which is highly endemic throughout Southeast Asia and caused several hundred hospitalizations in U.S. forces during the Vietnam conflict.<sup>118</sup> U.S. military personnel have presented with disease years after exposure in Vietnam.<sup>119</sup> Between 1987 and 1994, 23 acute cases were diagnosed in the Singapore Armed Forces.<sup>120</sup> Unlike patients from endemic areas who frequently have underlying illnesses or are elderly, soldiers are usually fit. The disease is probably underdiagnosed in soldiers as well as endemic populations because of failure of medical personnel to recognize its many clinical presentations and the lack of access to microbiologic assays.<sup>117</sup>

Parasitic infections that are transmitted by contact with contaminated soil, such as hookworm and strongyloides (see Chapters 110 and 111), have long been associated with deployed soldiers. During World War II, there were 23,300 hospitalizations of U.S. troops attributed to hookworm.<sup>121</sup> In a study of 500 American soldiers returning from Vietnam in 1965, 15% were infected with intestinal parasites (55% had hookworm, 19% had strongyloides, and 14% had both).<sup>122</sup> During 1983 after military intervention in Grenada, over 200 soldiers in different U.S. Army units reported signs and symptoms consistent with soil-transmitted helminthic infections.<sup>123</sup> Hookworm was confirmed in 8.3% of soldiers in one survey. Outbreaks of hookworm and strongyloides infections occurred repeatedly in U.S. troops training at the JOTC in Panama during the 1980s and 1990s.<sup>124</sup> In 1993, 566 soldiers from an infantry battalion trained for 3 weeks in Panama. Approximately 3 weeks after returning home, soldiers began to seek medical care for abdominal pain, nausea, vomiting, and diarrhea. An investigation identified hookworm infection in 12% of 75 soldiers who submitted a single stool sample and strongyloides in 3%. Eosinophilia (>7%) was detected in 129 of 473 blood samples, suggesting helminthic infection in 27% of the soldiers. These outbreaks demonstrated the importance of considering helminthic infections in troops exposed to muddy, contaminated soil. Many will present with gastrointestinal symptoms several weeks after exposure, but before eggs are observed in the stool. Soldiers should have a complete blood count with differential to document eosinophilia and uncover asymptomatic infections. Of particular concern to the long-term health of infected soldiers is the ability to detect strongyloides infections, which, if untreated, can lead to life-long infection and the possibility of life-threatening hyperinfection if the soldier/veteran becomes immunosuppressed.

## CONCLUSION

Not all infectious diseases that have been reported in modern military forces were discussed in this chapter. There was not enough space to present all the published evidence for the diseases that were included in the chapter. Individual cases of unique parasitic diseases that have been described in military personnel and sexually transmitted diseases and HIV infections were also not reviewed.

Although modern war has evolved substantially, and today's battlefield is quite different from previous conflicts, infectious diseases remain a major threat to deployed troops. Presently, large numbers of military personnel from many countries are sent to areas with high incidences of

infectious diseases. When their working and living conditions are crowded or unhygienic, particularly in times of war and conflict, their risk of infection increases. When appropriate public health and preventive measures are implemented, the incidence of infectious diseases can be greatly reduced. When military and civilian physicians who care for ill soldiers recognize their illnesses and institute appropriate therapies promptly, morbidity from infectious diseases can be lessened. However, even in these optimal circumstances, infectious diseases still occur.

When appropriate preventive measures are not instituted and treatment providers are not adequately prepared, attack rates from malaria, diarrheal diseases, acute respiratory infections, and other contagious infectious diseases can be quite high and deaths do result. Many nations do not have the resources to implement sound public health measures in their troops or to deploy sophisticated medical care. Although developed nations, such as the United States, may have the means to prevent and treat infectious diseases even in the most austere conditions, sometimes they do not implement the most effective preventive and curative services. Furthermore, with the speed of today's travel, deployed troops incubating an infectious illness may return home and present to garrison-based or civilian physicians. All physicians, whether they are with deployed troops or caring for those who returned home, need to be mindful of the exposures to infectious diseases and the illnesses that can occur in military settings. The ill soldier or veteran represents a high risk traveler that may have been exposed to various pathogens in many different countries.

## Gastrointestinal Symptoms

LUIS M. VALDEZ

### INTRODUCTION

We live in a changing world where the effects of rural-to-urban migration and international travel to and from tropical areas of the world underscore the importance of recognizing and understanding tropical infections. Because most developing countries are in the tropics, the poor sanitary conditions that exist in these areas favor the acquisition of infections in which the gastrointestinal tract is an important portal of entry for microbes. These infections may manifest in different ways, with signs and symptoms that may or may not be related to the gastrointestinal tract. Although gastrointestinal symptoms are many times nonspecific, it is important to recognize them in the context of the patient's environment, exposures, and immune status. The last in particular has become increasingly important in tropical areas, as the burden of human immunodeficiency virus (HIV) infection is linked to the social disorganization and increasing poverty seen in the tropical developing countries. It is estimated that greater than 90% of the world's acquired immunodeficiency syndrome (AIDS) cases occur in resource-poor regions, many of which are in the tropics.<sup>1</sup>

When assessing patients with gastrointestinal symptoms, it is important to remember that although these symptoms are usually related to enteric infections, they may be secondary to systemic infections or to complications from a previously acquired infection. For example, malaria may often present with diarrhea and mislead critical diagnostic evaluation. It is thus essential to obtain a careful history, with emphasis on environmental exposures, dietary habits, contacts, and immunizations (Box 123-1). Gastrointestinal symptoms in the tropics are diverse, and although some may be related to "nontropical" conditions, it is also important to remember that some tropical enteric infections may present with predominantly systemic symptoms.

### SYMPTOMS AND SYNDROMES

In tropical enteric infections, the presence of symptoms relates to organism virulence, the degree of infestation or inflammation caused by the infecting organism, and the host

### Box 123-1 Important Aspects of the History in Patients from Tropical Areas

immune response. In the case of some enteric infections, especially in children living in endemic areas, the presence of pathogenic organisms may not correlate with the existence of symptoms.<sup>2</sup> In studies in Egypt, looking at children with *Giardia* infection, the protozoan was found in symptomatic and asymptomatic children, and there was a failure to show an association between infection and symptomatic illness.<sup>3</sup> The same has been described in longitudinal studies in Peruvian children, where no association was found between a variety of enteropathogens and persistent diarrhea.<sup>4</sup> This argues against diagnosing and treating microbe-specific infections in areas where the risk of reinfection is high, although increasing evidence suggests that asymptomatic infections with organisms such as enteroaggregative *Escherichia coli*<sup>5</sup> and *Cryptosporidium*<sup>6</sup> may be associated with impaired growth, probably because of inflammatory responses and/or malnutrition caused by these pathogens. Studies looking at adult subjects with documented enteric parasitic infections corroborate the fact that symptoms may be absent, particularly in subjects from tropical areas who have migrated to areas where these infections are uncommon.<sup>7,8</sup>

We have classified gastrointestinal symptoms in the tropics into seven syndromes (Table 123-1), and it is important to consider that certain microorganisms may cause more than one syndrome. In many infections, specific therapies are available (Table 123-2), but in some diseases, when the symptoms are a result of the host response to the infection, antimicrobial agents are ineffective.

Although systemic symptoms may be even nonspecific, it is important to recognize that some enteric tropical infections may present without a predominance of enteric symptoms. Such is the case, for example, of *Cyclospora cayetanensis* infections, where symptoms of profound fatigue, anorexia, and weight loss often predominate over the diarrheal symptoms.<sup>9</sup>

### Enteric Fever

Enteric infections can cause clinical syndromes in which fever is predominant, sometimes associated with abdominal pain, in a protean clinical picture distinctive from other acute

**Table 123-1** Syndromes (and Their Most Common Causes) in Patients with Gastrointestinal Symptoms in the Tropics

Syndrome	Agent/Condition	Organisms	Differential Diagnosis
Enteric fever	Bacteria	Typhoid fever ( <i>Salmonella typhi</i> ) Salmonellosis (non- <i>S. typhi</i> ) Brucellosis Yersiniosis (rare) <i>Campylobacter</i> (rare)	Tuberculosis Acute schistosomiasis Malaria Septicemic plague Abdominal anthrax
Oral lesions	Bacteria Mycobacteria Fungi Protozoa Viruses	Noma (children), syphilis (primary or secondary), actinomycosis, oral anthrax Tuberculosis, leprosy Paracoccidioidomycosis Histoplasmosis, candidiasis Mucocutaneous leishmaniasis Herpes simplex	
Dysphagia	Protozoa Fungi Viruses	Trypanosomiasis Candidiasis (AIDS) Herpes simplex (AIDS) Cytomegalovirus (AIDS)	Esophageal cancer
Bleeding	Upper gastrointestinal bleeding Peptic ulcer disease Lower gastrointestinal bleeding	Esophageal varices: chronic schistosomiasis, cirrhosis (hepatitis B and C) <i>Helicobacter pylori</i> infection Typhoid fever, nonspecific colitis Tuberculosis (rare), amebiasis (rare)	Stomach cancer Polyps, colon cancer Diverticulosis
Abdominal pain	Peptic ulcer disease Intestinal parasitosis	<i>H. pylori</i> <i>Ascaris lumbricoides</i> , <i>Strongyloides stercoralis</i> , <i>Angiostrongylus costaricensis</i> , <i>Anisakis marina</i> , hookworm	Appendicitis Complicated hernia Intussusception
Abdominal mass	Bacteria Parasites Fungi	Tuberculosis Typhoid (perforation) Tuberculosis, actinomycosis Ameboma, <i>Angiostrongylus</i> Histoplasmosis	Colon cancer, lymphoma
Diarrhea	Watery diarrhea and gastroenteritis Inflammatory diarrhea Persistent diarrhea Traveler's diarrhea	ETEC, EAEC, <i>Vibrio cholerae</i> O1 and non-O1, <i>Salmonella</i> , <i>Shigella</i> , <i>Campylobacter</i> , <i>Staphylococcus aureus</i> and <i>Bacillus cereus</i> (toxin-mediated), <i>Cryptosporidium parvum</i> , <i>Cyclospora cayetanensis</i> , <i>Isospora belli</i> , viruses (rotavirus and others) <i>Shigella</i> , <i>Salmonella</i> , <i>Campylobacter</i> , <i>Entamoeba histolytica</i> , <i>Balantidium coli</i> EAEC, tuberculosis, <i>Giardia lamblia</i> , <i>C. parvum</i> , <i>Cyclospora</i> , <i>I. belli</i> , <i>S. stercoralis</i> , <i>Capillaria philippinensis</i> ETEC, EAEC, <i>Shigella</i> , <i>Campylobacter jejuni</i> , <i>Aeromonas</i> , <i>Plesiomonas shigelloides</i> , <i>Salmonella</i> , <i>Giardia</i> , <i>Cryptosporidium</i> , <i>Cyclospora</i>	Tropical sprue, Brainerd diarrhea Lymphoma

AIDS, acquired immunodeficiency syndrome; EAEC, enteroadherent *Escherichia coli*; ETEC, enterotoxigenic *E. coli*.

enteric processes. Usually the portal of entry in these infections is the gastrointestinal tract, but the differential diagnosis includes other infections and some noninfectious conditions. The classic infections causing enteric fever include typhoid fever, caused by *Salmonella typhi*, and the nontyphoid salmonellosis, brucellosis, yersiniosis, and *Campylobacter* infections. What characterizes these infections is the gastrointestinal portal of entry and the intracellular nature of the infection, where the organisms multiply in the lymphoid tissue before disseminating.

Typhoid fever caused by *S. typhi* is the classic prototype of enteric fever and still represents an important cause of morbidity and mortality in areas where it is endemic.<sup>10</sup> It is

estimated that there are 16.6 million cases of typhoid fever each year with 600,000 deaths.<sup>11</sup> Although the syndrome classically is characterized as an acute illness with fever, headache, and abdominal pain, the symptoms are relatively nonspecific and the differential diagnosis, especially when there is associated splenomegaly, should include malaria, brucellosis, amebic liver abscess, visceral leishmaniasis, and viral syndromes such as dengue, depending on the geographic area from which the patient comes. Delays in the diagnosis of typhoid fever should be avoided, since complications can ensue. The complications in typhoid fever may be related directly to dissemination of *S. typhi* (meningitis, endocarditis, bone lesions), to the systemic inflammatory

**Table 123-2 Recommended Antimicrobial Therapy for Adults Infected by Selected Organisms Causing Gastrointestinal Disease in the Tropics\***

Organisms	Therapy
Typhoidal syndrome	Ciprofloxacin 500 mg po bid × 10–14 days <i>or</i> Ceftriaxone 2.0 g IV × 10–14 days <i>or</i> Chloramphenicol 50 mg/kg/day po qid (max daily dose 3 g) × 14 days <i>or</i> Ofloxacin 15 mg/kg po qd × 7 days <i>or</i> Cefixime 200 mg po q12h × 14 days
Brucellosis	Doxycycline 100 mg po bid × 6 wk + streptomycin 1 g qd IM × 2 wk
<i>Helicobacter pylori</i>	Clarithromycin 500 mg po bid + omeprazole 40 mg po qd × 14 days <i>or</i> Metronidazole (250 mg po tid) + amoxicillin (500 mg po qid) + bismuth subsalicylate (2 × 262-mg tablets qid) × 14 days
<i>Vibrio cholerae</i> O1	Tetracycline 500 mg po qid <i>or</i> doxycycline 100 mg po × 3 days <i>or</i> Doxycycline 300 mg po × 1 <i>or</i> Ciprofloxacin 250 mg po q12h × 3 days
<i>V. cholerae</i> , non-O1	Tetracyclines <i>or</i> ciprofloxacin
<i>Shigella</i>	Resistant to furazolidone and trimethoprim-sulfamethoxazole Ciprofloxacin 500 mg q12h × 3 days <i>or</i> Norfloxacin 400 mg q12h × 3 days
<i>Campylobacter</i>	Erythromycin 500 mg po qid × 5 days <i>or</i> other macrolides as above
<i>Salmonella</i>	Therapy not indicated unless severe or in a host susceptible to bacteremic complications; fluroquinolones × 7–10 days
<i>Giardia lamblia</i>	Metronidazole 250 mg po tid × 5 days <i>or</i> Tinidazole 2.0 g × 1 dose <i>or</i> Quinacrine 100 mg po tid × 5 days
<i>Entamoeba histolytica</i>	Metronidazole 750 mg po tid (500 mg IV q6h) × 10 days <i>or</i> Tinidazole 1.0 g po q12h × 3 days <i>or</i> Tetracycline 500 mg po qid × 14 days
<i>Cyclospora cayetanensis</i>	All followed by iodoquinol 650 mg po tid × 20 days
<i>Cryptosporidium parvum</i>	Trimethoprim-sulfamethoxazole 1 double-strength bid po × 3–7 days No effective therapy demonstrated in adults Paromomycin 500 mg po qid (partial response, used in patients with AIDS) Nitazoxanide 500–1000 mg bid × 14 days (response in some patients with AIDS)
<i>Isospora belli</i>	Trimethoprim-sulfamethoxazole 1 double-strength po qid × 10 days then bid × 3 wk
<i>Balantidium coli</i>	Tetracycline 500 po qid × 10 days <i>or</i> Metronidazole 750 mg po tid × 5 days <i>or</i> Paromomycin 500 mg po tid × 7 to 10 days
<i>Ascaris lumbricoides</i>	Mebendazole 100 mg po bid × 3 days <i>or</i> Pyrantel pamoate 11 mg/kg po qd × 3 days <i>or</i> Albendazole 400 mg po single dose
<i>Strongyloides stercoralis</i>	Thiabendazole 22 mg/kg po bid × 2 days <i>or</i> Albendazole 400 mg po qd × 3 days <i>or</i> Ivermectin 200 µg/kg/day × 2 days

\*Duration of therapy for nonimmunocompromised patients. Duration of therapy will be prolonged in patients with AIDS.

response secondary to the infection (typhoid state), or to direct involvement of the gut resulting in hemorrhage, perforation, and ileus.<sup>12</sup> Other salmonella (especially *S. paratyphi* A and B, *S. choleraesuis*, and other *Salmonella* serotypes) may also cause a typhoidal clinical syndrome.<sup>13</sup>

Acute brucellosis is another cause of enteric fever in which systemic symptoms predominate over those symptoms related to the gastrointestinal tract. In a recent fever surveillance study in Egypt, 87% of patients with brucellosis were actually diagnosed with and treated for typhoid.<sup>14</sup> Anorexia, abdominal pain, vomiting, and diarrhea or constipation are some of the complaints elicited in patients with brucellosis if the patient is carefully questioned.<sup>15</sup> In areas where brucellosis is endemic, it is important to obtain a detailed history assessing ingestion of unpasteurized milk or cheese, as well as occupational exposures.

*Yersinia enterocolitica* infections, although found in tropical areas, are rarely a cause of tropical diarrhea,<sup>16</sup> and the

septicemic disease is seen mostly in patients with underlying predisposing factors and chronic diseases.

Some zoonoses, such as plague and anthrax, can occasionally present with a clinical picture suggestive of enteric fever, so epidemiologic information is essential to the diagnosis of these conditions. Septicemic plague, for example, can sometimes present with prominent gastrointestinal symptoms (nausea, vomiting, diarrhea, and abdominal pain), symptoms that may precede the development of a bubo, or even be part of septicemic plague, in which no bubo is recognized. In a review of 71 human plague cases, gastrointestinal symptoms occurred in 57% of the patients, with nausea and vomiting being the most common symptoms and diarrhea and abdominal pain occurring less often (28% and 17% of patients, respectively).<sup>17</sup> In disease caused by *Bacillus anthracis* following the ingestion of contaminated food, abdominal anthrax will present after an incubation period of 2 to 11 days.<sup>18</sup> Symptoms initially may be nonspecific, with fever, anorexia,

nausea, and vomiting. As the disease progresses, abdominal pain, hematemesis, and bloody diarrhea will often develop.

Two other conditions that have to be considered in the differential diagnosis of fever and enteric symptoms are tuberculosis and schistosomiasis. In patients with intestinal tuberculosis, although they may have associated pulmonary disease, some series have found evidence of active or remote pulmonary tuberculosis in as few as 25% of cases, the diagnosis being an unexpected finding at exploratory laparotomy.<sup>19</sup> Patients with acute schistosomiasis (Katayama fever) may also present with an enteric fever syndrome. Typically, this occurs in subjects who are not residents of endemic areas, and it is believed to be in relationship to the host response to the parasite.<sup>20</sup> The history of swimming in freshwater during the previous month in areas in which schistosomiasis is endemic also favors this diagnosis.

It is important to recognize the endemicity of certain tropical diseases in order to recognize infections like typhoid fever and those that are unusual in other geographic settings. When approaching patients with enteric fever, it is thus essential to obtain a complete history and to do a complete physical examination looking for clinical clues that may suggest one process or another. Microbiologic diagnosis should be attempted whenever possible, but in some tropical areas this may not be feasible and in the case of typhoid the diagnosis may rely on serologic methods (Widal's test) and a suggestive clinical picture.<sup>21</sup> In an Indian study, Widal's test was acceptable as a diagnostic tool, with a high specificity and positive predictive value when an O-antigen 1:160 dilution defined a positive result in the presence of a suggestive clinical picture.<sup>22</sup> In the same study, the same titer was observed in 10.2% of patients with other febrile illnesses of known cause and in 1.8% of normal children. Studies in nonendemic areas also show that the test can give a significant number of false positives.<sup>23</sup> The diagnosis of typhoid fever by Widal's test alone is prone to error and there are no universally applicable criteria for the serologic diagnosis. In areas where microbiologic diagnosis is not possible, Widal's test should only be considered a sensitive and specific "fever screen" for typhoid, but it has to be recognized that it will not identify all cases and may give some false positives. In areas where malaria is endemic, false positives have been described; in one study, Widal's test was found to be positive in 15% and 10% of malaria patients for salmonella O- and H-antigen titers, respectively.<sup>24</sup> In areas where malaria is also endemic, typhoid fever and malaria always have to be considered in the differential diagnosis of an acute febrile illness, so a thick smear in addition to cultures for *Salmonella* should be obtained. For the microbiologic diagnosis of typhoid fever, blood and stool cultures have been recommended traditionally for the isolation of *S. typhi*, but bone marrow cultures and duodenal string cultures (duodenal string-capsule culture) provide a higher yield. In a Peruvian study in adult patients with documented *S. typhi* infection, duodenal content cultures were as sensitive as bone marrow in providing a diagnosis (86% and 75% sensitivity, respectively) compared with blood (42%) and stool (26%) cultures.<sup>25</sup> Bone marrow and duodenal string cultures also remain positive for a longer period despite antibiotic therapy, and thus may be useful in patients who have received empirical antibiotic therapy and in whom a microbiologic diagnosis is needed.<sup>25,26</sup> In older pediatric

patients, the duodenal string method has also been shown to be better than blood cultures,<sup>27</sup> but in smaller children it may not be practical.<sup>27,28</sup>

The treatment of patients with acute enteric fever syndromes should be based on an etiologic diagnosis, but at times empirical therapy may be necessary while awaiting culture results. In the case of typhoid fever, delays in diagnosis and treatment should be avoided because of the impact of therapy on disease mortality and on the incidence of intestinal hemorrhage.<sup>12</sup> When treating patients with typhoid fever one has to consider that strains of *S. typhi* that are resistant to the three first-line antibiotics (chloramphenicol, amoxicillin, and trimethoprim-sulfamethoxazole) have been described in many tropical countries,<sup>29</sup> so it is essential to know the local resistance patterns in each endemic area. These multiresistant organisms are typically susceptible to third-generation cephalosporins and to the fluoroquinolones,<sup>30,31</sup> but responses have been slower with the cephalosporins. In an open study comparing ceftriaxone (2 g per day for 5 days) with fleroxacin (400 mg once a day for 7 days), the mean fever clearance times were 160 hours and 81 hours, respectively, and there were two failures in the ceftriaxone group and none in the fleroxacin group.<sup>32</sup> In another study comparing ceftriaxone (3 g per day for 7 days) with ciprofloxacin (500 mg twice a day for 7 days), there were six failures (out of 22 patients) in the ceftriaxone group and none in the ciprofloxacin group.<sup>33</sup> Oral cefixime has been studied in children with multidrug-resistant typhoid in Pakistan, but failures were reported in 3 of 50 patients (6%).<sup>34</sup> Fluoroquinolones are currently considered the drugs of choice for patients with multidrug-resistant typhoid, although there have been reports of ciprofloxacin resistance from India and in travelers returning to the United Kingdom after travel to the Indian subcontinent.<sup>35,36</sup> Fluoroquinolone-resistant strains, which are often multidrug-resistant are best treated with either azithromycin (which also covers quinolone-resistant *Campylobacter*) or cephalosporins.<sup>37</sup> Short courses of fluoroquinolones have been used in Vietnam for the treatment of typhoid. In one of the studies, involving 438 patients (286 were younger than 14 years old), two short-course regimens of ofloxacin (15 mg/kg per day for 3 days vs. 10 mg/kg per day for 5 days) were assessed and there was only one failure in one patient who took only one dose.<sup>38</sup> Table 123-2 summarizes the most accepted regimens for treating typhoid, and the antibiotics should be used based on the knowledge of the local patterns of resistance, cost, compliance, and safety. Although short-course treatments using fluoroquinolones may improve compliance and reduce costs, these short-course treatments should also be evaluated in other geographic areas before they can be recommended elsewhere.

### Oropharyngeal Lesions

Bacterial, fungal, parasitic, and viral infections can all give rise to oropharyngeal lesions. The first three types present with increased frequency in the tropics.

Among the bacterial infections causing oral lesions seen in tropical areas, one seen with an increased incidence in West Africa is noma (cancrum oris), a severe gangrene of the soft and hard tissues of the mouth, face, and neighboring areas.

*Fusobacterium necrophorum*, along with other organisms, has been implicated in its pathogenesis. These opportunistic pathogens invade oral tissues in children whose immune system is weakened by malnutrition, acute necrotizing gingivitis, debilitating conditions, trauma, and other oral mucosal ulcers.<sup>39</sup>

Considering the increasing prevalence rates for sexually transmitted diseases in developing countries, orogenital contact can result in oral and oropharyngeal lesions of syphilis. Secondary syphilis can also present with painful oral ulcerations or oral condyloma lata lesions.<sup>40,41</sup> In contrast with the oral lesions of primary syphilis, which tend to be solitary, painless, indurated, and punched-out ulcers, oral lesions of secondary syphilis are typically painful and multiple and are accompanied by a generalized rash.

Actinomycosis, anthrax, tuberculosis, and leprosy can also present with oral lesions. Actinomycotic infections of the cervicofacial area are rare, and the most common presentation is an acute painful swelling associated with a soft tissue abscess secondary to dental lesions.<sup>42</sup> Rare cases of oral actinomycosis may mimic neoplasms of the tongue.<sup>43</sup> Oral anthrax is characterized by a mucosal lesion in the oral cavity or oropharynx which can progress to pseudomembranous necrosis, and to cervical adenopathy and edema.<sup>44</sup> Primary tuberculosis of the mouth may present with painless ulcerations of long duration and enlargement of the regional lymph nodes.<sup>45</sup> Lepromatous leprosy can cause oral lesions in 20% to 60% of patients. Oral lesions are often an extension of disease in the nasal mucous membranes. Oral lesions are characterized as hemorrhagic sessile nodules involving the maxillary incisive papilla, lips, tongue, soft palate, uvula, and glossopharyngeal arches.<sup>46</sup>

Among the fungal infections in the tropics, paracoccidioidomycosis (South American blastomycosis), histoplasmosis, and candidiasis can present with oral lesions. Oral lesions may be the first sign of paracoccidioidomycosis. Patients may present with chronic, proliferative, mulberry-like ulcerated oral lesions. Typically the gingiva or alveolar process is affected, but lesions can be seen on the palate and lip. Most patients with oral lesions have detectable pulmonary involvement.<sup>47</sup> In disseminated histoplasmosis, lesions of the oral mucosa may be found in 30% to 50% of cases. Oral lesions may involve the lips, tongue, gingiva, and palate.<sup>48</sup> Oral candidiasis can be associated with malnutrition and debilitating diseases, but within the current AIDS epidemic its presence should raise the possibility of HIV infection.

Among the protozoan infections, mucocutaneous leishmaniasis can present with oral lesions. Patients with infection by *Leishmania viannia braziliensis* in Latin America may develop mucosal lesions of the nose, mouth, pharynx, or larynx months to years after the primary infection.<sup>49</sup> Other protozoal and helminthic infections may be associated on very rare occasions.<sup>50</sup>

## Dysphagia

Many of the conditions causing oral lesions in tropical areas can present with dysphagia. In this section, we concentrate on infectious processes that may affect primarily the esophagus.

In areas where *Trypanosoma cruzi* infection (Chagas' disease) is endemic, esophageal symptoms like dysphagia and regurgitation may be secondary to motor disorders related to this parasitic disease.<sup>51</sup> The involvement of the esophagus encompasses a spectrum with megaesophagus at the most severe end to milder variants without evidence of esophageal dilation in subjects who have documented serologic evidence of infection with *T. cruzi*.

Dysphagia and odynophagia may present secondary to infectious esophagitis, a condition known to occur with increased frequency in patients with HIV infection.<sup>52</sup> *Candida* esophagitis is by far the most common cause of esophageal symptoms in patients with HIV infection, accounting for 50% to 100% of symptomatic patients, and may occur in asymptomatic patients. After *Candida*, the most common causes of esophageal disease in symptomatic patients are cytomegalovirus (CMV), herpes simplex, and idiopathic esophageal ulcers.

Among the noninfectious pathologic conditions, esophageal cancer is unevenly distributed within the tropical regions; its prevalence rate is higher in East and South Africa and in the Far East. In these areas, this must be a consideration when assessing patients with esophageal symptoms.<sup>53</sup>

## Gastrointestinal Bleeding

Apart from the usual noninfectious causes of gastrointestinal bleeding, some infectious conditions in the tropics may present in this way. For example, enterohemorrhagic *E. coli* (EHEC) can cause bloody diarrhea in the tropics as in increasing outbreaks in industrialized temperate areas.

In schistosomiasis, the existence of periportal fibrosis leads to portal hypertension and varices with the resultant risk of gastrointestinal bleeding, representing an important cause of morbidity and mortality in endemic areas due to the large number of infected subjects.<sup>54</sup> In a field study in an area of the Sudan endemic for *Schistosoma mansoni*, the prevalence of esophageal varices in subjects undergoing esophagoscopy ranged between 54% and 67%. The varices were usually asymptomatic, with symptomatic varices (with a positive history of hematemesis) occurring in 3% to 4% of subjects with sonographic evidence of liver periportal fibrosis.<sup>55</sup> Abdominal ultrasound can accurately measure liver and spleen size and configuration and detect and grade periportal fibrosis and portal hypertension, and these findings can predict the risk of variceal bleeding in patients with complicated schistosomiasis.<sup>56</sup>

Another infectious condition that may present with gastrointestinal bleeding is typhoid fever, typically resulting from necrotic erosion of a Peyer's patch into an enteric vessel.<sup>37</sup> If untreated, it may result in passage of gross blood in the feces or melena in 10% to 20% of patients, with severe gastrointestinal bleeding occurring in 2% of patients late in the course of the disease.<sup>12</sup> Early treatment of typhoid fever will reduce the frequency of this complication, so in endemic areas for typhoid rapid diagnosis and therapy should be established.

Gastrointestinal tuberculosis on rare occasions can present with gastrointestinal bleeding. There have been case reports describing upper gastrointestinal bleeding from a tuberculous gastric ulcer and from esophageal tuberculosis.<sup>57,58</sup>

Reports of massive rectal bleeding from colonic tuberculosis have also been published.<sup>59,60</sup> Amebiasis, which commonly presents with bloody stools, on rare occasions may present with massive gastrointestinal bleeding requiring surgical therapy.<sup>61</sup>

In patients with lower gastrointestinal bleeding, colonoscopic examination may provide the diagnosis in a majority of patients. In a study of lower gastrointestinal bleeding carried out in a tropical area of India, predominant lesions in 138 adults were nonspecific colitis and ulcers (58%), polyps (19%), cancer (10%), rectal varices (4%), and tuberculosis (3%), with most lesions involving the left colon. Diffuse lesions were seen when nonspecific colitis and ulcers were the source of bleeding.<sup>62</sup> In another study from India, of 166 patients who underwent colonoscopy, a diagnosis could be made in 85%. Major causes of lower gastrointestinal bleeding included idiopathic ulcerative colitis (19.3%), acute colitis (12.0%), colonic polyps (10.2%), radiation colitis (9.0%), solitary rectal ulcer (7.8%), and colonic carcinoma (7.2%). Among the infectious conditions, colonic tuberculosis was found in 4.2% and enteric fever in 3.0%.<sup>63</sup>

### Abdominal Pain

The causes of abdominal pain are diverse, and enteric tropical infections certainly represent a definite group in the differential diagnosis in patients from tropical areas. Abdominal pain can be acute or chronic, and sometimes be part of an acute abdominal syndrome that may require a surgical approach. It is thus essential to recognize the common tropical diseases that may present with abdominal pain within the different tropical areas of the world.

Epigastric abdominal pain of gastric or duodenal origin can be linked to *Helicobacter pylori* infection, and there is definite evidence of a link between this organism and peptic ulcer disease and chronic gastritis, and epidemiologic evidence supporting its role in gastric cancer and lymphoma.<sup>64</sup> Gastric *H. pylori* infection is very common throughout the tropics, as evidenced by serologic surveys, yet active gastric infection does not always correlate with the incidence of serious upper gastrointestinal changes.<sup>65</sup> In a study in patients examined by gastroscopy for dyspepsia in northern Nigeria, 176 (92%) of 193 with acceptable biopsies had gastritis. *H. pylori* was present in 161 of 192 patients (84%): in 31 of 41 (75%) with chronic gastritis and in 130 of 135 (96%) with active gastritis.<sup>66</sup> Considering the role of *H. pylori* in gastritis, dyspepsia, peptic ulcer disease, and possibly gastric cancer, eradication of this infection should be attempted, although the cost of therapy may be difficult to justify in developing tropical areas.

Abdominal pain can also be a nonspecific symptom of intestinal parasitosis,<sup>67</sup> and in travelers to exotic areas the absence of symptoms should not preclude examination of the stools looking for parasites.<sup>8</sup> Although ascariasis is rarely a cause of abdominal pain, in a study in Nigeria assessing 865 patients with suspected peptic ulcer disease, 175 patients (20%) were found to have *Ascaris* infection, and their symptoms resolved after the use of anthelmintics.<sup>68</sup> Interestingly, the diagnosis of ascariasis was done radiologically as part of the workup for the diagnosis of peptic ulcer disease. The authors proposed that in areas with a high prevalence of

ascariasis, a stool examination should be part of the assessment in patients with uncomplicated suspected peptic ulcer disease. Hookworm may also be associated with abdominal pain and eosinophilia in the tropics, presenting several weeks before ova are shed to aid in the diagnosis.<sup>69</sup>

Among the causes of chronic abdominal pain in the tropics, when there is an association with ascites, the possibility of tuberculous peritonitis should be considered. The presentation of peritoneal tuberculosis is quite insidious, with most patients having symptoms for weeks or months before seeking medical attention. Marshall,<sup>70</sup> in a review of tuberculosis of the gastrointestinal tract and peritoneum, summarized data from six large series in the literature (two from tropical countries). In his review, abdominal pain was present 58% of the time, and the most common symptom was abdominal distention (about 82% of the cases). Other common symptoms included fever and weight loss. The ascitic fluid is an exudate with a lymphocytic predominance in the white blood cell differential count. The diagnostic yield from smears and cultures from the ascitic fluid is very low, although Singh and colleagues<sup>71</sup> reported 83% positive cultures when culturing 1 L of fluid concentrated by centrifugation. Currently, the best diagnostic test is laparoscopic biopsy of the peritoneum. Simply the gross appearance of the peritoneal cavity during laparoscopy allows a presumptive diagnosis in 85% to 95% of patients, and caseating granulomas are found from the biopsy specimens in 85% to 90% of cases.<sup>70,72</sup> The measurement of adenosine deaminase activity (ADA) has been reported as a sensitive way of making a presumptive diagnosis.<sup>73</sup>

Abdominal pain can also be the presenting symptom of an acute abdomen, and in the tropics, apart from the usual pathologic changes seen in other areas, certain infectious conditions should be considered in the differential diagnosis.

In the case of appendicitis, the most common abdominal surgical emergency in nontropical areas, pathologic studies in tropical areas have shown that in a few cases infection can be detected. In a pathologic study of 2921 appendectomies in a tropical area over a 25-year period, 70 (2.3%) specimens showed typical evidence of tuberculosis. Parasitic infestation was detected in 75 (2.5%), including enterobiasis (1.4%), amebiasis (0.5%), ascariasis (0.5%), ascariasis with trichuriasis (0.05%), and taeniasis (0.05%).<sup>74</sup>

Intestinal obstruction in patients living in tropical areas can be caused by external hernia, sigmoid volvulus, intussusception (particularly in children), and ascariasis.<sup>75,76</sup> In a prospective evaluation of acute intestinal obstruction in 3550 consecutive patients in Africa, the majority of patients (75%) had an external hernia.<sup>75</sup> However, *Ascaris* infection in children, volvulus of the sigmoid colon in adults, and intussusception in both children and adults were significant causes of abdominal obstruction in 18% of the patients. In highly parasitized children, a mass of *Ascaris* adult worms can cause acute small bowel obstruction, although in most cases the obstruction is not complete and conservative measures and anthelmintic therapy can obviate the need for surgery.<sup>77</sup> *Strongyloides stercoralis* has also been reported, presenting as a subacute intestinal obstruction in two patients from Iraq.<sup>78</sup> Gastrointestinal tuberculosis can sometimes present with a subocclusive or obstructive picture. In a series of 300 cases of abdominal tuberculosis that required surgical therapy,

Bhansali<sup>79</sup> found that of the 139 patients that presented with abdominal pain, 92 had abdominal obstruction, 23 had perforation, and 19 presented with peritonitis. In 56 of the patients, the acute episode was the first manifestation of abdominal tuberculosis, while the other 83 had a previous history of chronic abdominal pain for a period of time that ranged from 1 month to more than 10 years. Only 10% of the patients had active pulmonary or pleural tuberculosis, and another 12% gave a history of previous tuberculosis, or their chest films showed a past, healed focus. Obstruction can be secondary to narrowing of the lumen by hyperplastic cecal tuberculosis, strictures of the small intestine, adhesions, or be related to extrinsic compression of the bowel by mesenteric lymph nodes. In approaching patients with abdominal pain in tropical areas where tuberculosis is prevalent, this diagnostic possibility should always be considered.

One of the most lethal complications of typhoid fever is ileal perforation, which should be considered if an acute abdomen develops in a patient with prolonged fever. The most important sign is pneumoperitoneum on plain abdominal film. This complication requires surgical therapy, usually consisting of simple closure and irrigation of the peritoneal cavity.<sup>80</sup> In a review of the literature published after 1960 on typhoid perforation in different developing countries, information was obtained on a total of 1990 cases of typhoid perforation in 66,157 patients with typhoid fever, published in 52 reports from all over the world.<sup>81</sup> The overall frequency of intestinal perforation in typhoid fever was 3% with an overall mortality rate of 39.6%. In a recent report from Turkey,<sup>82</sup> mortality decreased significantly, from 28% to 10%, with the institution of aggressive fluid resuscitation and appropriate antibiotic therapy in the preoperative period, and total parenteral nutrition to provide adequate metabolic support during the postoperative period. Apart from specific antibiotic therapy against *S. typhi*, broad-spectrum antibiotics should be added to cover enteric flora (mainly anaerobes and gram-negative organisms).

The tropical spectrum of generalized peritonitis is different from the Western spectrum. In a study in India, of a total 155 cases of generalized peritonitis that were surgically treated, the most common cause of peritonitis was peptic ulcer perforation followed by typhoid perforation. Other causes of peritonitis in the same study were appendicular perforations, tubercular perforations (sometimes with a previous history of subacute intestinal obstruction and evidence of pulmonary tuberculosis), and ruptured amebic liver abscess.<sup>83</sup> Amebic perforation of the colon has also been described in patients presenting with an acute abdomen and a past history of fever, pain, and diarrhea.<sup>84</sup>

It is important in tropical areas to identify nonsurgical infectious causes of abdominal pain that may mimic an acute abdomen. *Angiostrongylus costaricensis* is found in areas of Central and South America and infections in children caused by this organism may present with fever, anorexia, vomiting, and right lower quadrant or flank pain or mass, suggesting a classic case of appendicitis. In a study in Costa Rica, more than three fourths of children found to have *A. costaricensis* underwent surgery.<sup>85</sup> Ileocecal tuberculosis, amebiasis, and salmonellosis may also mimic appendicitis, although a more prolonged story of pain or fever may differentiate them from acute appendicitis. Patients with mesenteric adenitis may also

have an illness clinically indistinguishable from acute appendicitis, although this condition has been reported mostly in nontropical areas. Anisakiasis, although not typical of tropical areas, is a disease caused by the larval nematode *Anisakis marina* ("herring worm") and is associated with eating raw fish. It is a recognized public health problem in Japan, and cases have been reported in Europe. The intestinal burrowing of the larval form causes acute abdominal symptoms clinically resembling acute appendicitis.<sup>86</sup>

## Abdominal Mass

Among the infectious conditions that can present with an abdominal mass, tuberculosis should be in the differential diagnosis. Primary intestinal tuberculosis may present with abdominal pain, fever, and a tender, fixed palpable mass in the ileocecal area.<sup>87</sup> Bhansali,<sup>79</sup> in his series of patients with tuberculosis requiring surgery, found 96 patients who had a palpable mass on physical examination, and all of these patients had a chronic presentation. In 75 of these patients, the mass was caused by hyperplastic cecal tuberculosis, in 19 it was due to a mass of enlarged lymph nodes, and in the remaining 2 it was related to rolled-up omentum. Common symptoms in these patients were fever, weight loss, altered bowel habits, and chronic abdominal pain. Although uncommon in nonimmunocompromised persons, tuberculosis can involve the mesenteric lymph nodes and present with abdominal pain, fever, a palpable mass, or symptoms of partial small bowel obstruction.<sup>88</sup> In contrast, in patients with AIDS tuberculosis, mesenteric lymphadenitis is more common and generally more extensive.<sup>89</sup>

Another infectious condition that may present with a mass is abdominal actinomycosis. The cecal area is most frequently the site of abdominal actinomycosis, and it can present as an abscess or as a firm-to-hard mass lesion that is often fixed to the underlying tissue. Sinus tracts may develop, draining through the abdominal wall or perianal region.<sup>90</sup> Amebiasis can present as a chronic localized infection termed *ameboma*. An ameboma presents as a painful abdominal mass that occurs more commonly in the cecum or the ascending colon.<sup>91</sup>

Other tropical infectious disease conditions that may present with an abdominal mass are histoplasmosis<sup>92</sup> and *A. costaricensis* infection (described previously). Histoplasmosis involving the gastrointestinal tract usually occurs with disseminated disease. Gastrointestinal histoplasmosis differs from other forms of disseminated histoplasmosis in that pulmonary symptoms are uncommon and gastrointestinal symptoms predominate. Common symptoms, although they may be absent in as many as 50% of cases, include diarrhea, weight loss, abdominal pain, and fever. Clinically, patients may also present with generalized lymphadenopathy and hepatosplenomegaly. Histoplasmosis involving the gastrointestinal tract most frequently is characterized by ulcerations or an intestinal mass, especially when there is involvement of the terminal ileum, cecum, or colon.<sup>92</sup>

## Diarrhea

Diarrheal diseases, despite major scientific advances, are a major cause of morbidity, and their frequency in the tropical

areas of the world underscores the global impact of tropical diseases.<sup>93</sup> In these areas, diarrhea is a common cause of infant mortality, and diarrheal morbidity and mortality are linked with the poverty and sanitary deficiencies commonly seen in developing areas. For people from nontropical developed areas visiting the tropics, it also represents an important cause of morbidity, since it can affect 20% to 50% of travelers.<sup>94</sup>

When approaching patients with diarrhea, it is important to obtain a good history and to define the clinical syndrome: acute watery diarrhea (small bowel disease), profuse vomiting (gastroenteritis), dysenteric disease, or persistent diarrhea.

### Acute Watery Diarrhea

Acute watery diarrhea is characterized by the presence of large-volume stools and is usually associated with a small bowel secretory process. The causes of acute watery diarrhea are different in temperate climates compared with tropical areas. In temperate climates, the usual causative organisms are largely undefined, although viruses are suspected in many cases. In the tropics, where most adults live in areas with poor sanitation, several other agents can cause acute noninflammatory diarrhea. Of particular importance are enterotoxigenic *Escherichia coli* (ETEC) diarrhea and cholera. Enteraggregative *E. coli* (EAEC) is an enteric pathogen showing increasingly recognized importance as a cause of worldwide diarrhea mediated by intestinal inflammatory mechanisms causing watery, nonbloody diarrhea. EAEC is an important cause of persistent diarrhea in infants in the developing world, travelers' diarrhea, and AIDS-associated diarrhea in many regions.

The seventh pandemic, caused by *Vibrio cholerae* biotype El Tor, has affected most of the continents of the Eastern Hemisphere, including Asia, Africa, and the Mediterranean region of Europe. In 1991, the organism appeared in Peru and spread throughout Latin America.<sup>95</sup> Peru alone reported 322,562 cases, half of which occurred during the first 12 weeks of the epidemic. A new strain of the non-O1 serogroup, *V. cholerae* O139 synonym Bengal, was seen in late 1992, beginning in Madras, India, and rapidly spreading to Calcutta and Bangladesh in 1993, causing epidemic cholera gravis.<sup>96,97</sup> This may represent the beginning of an eighth pandemic.<sup>98</sup> The hallmark of this disease is a secretory diarrhea induced by an enterotoxin, commonly referred to as cholera toxin, which produces water and electrolyte losses in the intestinal lumen resulting in dehydration ranging from mild to severe. In endemic areas, the differential diagnosis in cases of mild to moderate disease should include infections produced by ETEC, food poisoning, and viruses such as rotavirus (especially in children).

Other bacterial pathogens, such as *Shigella*, *Salmonella*, and *Campylobacter jejuni*, which typically cause inflammatory diarrhea, may occasionally present with a clinical picture of acute watery diarrhea. Because it is not possible to differentiate between these infections solely on clinical grounds, the assistance of a microbiology laboratory is advised, although in remote areas in the tropics it is not always possible to obtain a properly equipped and staffed laboratory facility. To make the diagnosis of cholera bacteriologically, one should culture stool specimens onto thiosulfate-citrate-bile salts-sucrose (TCBS) agar.

Initial management of these patients should include adequate fluid replacement, preferably orally with glucose electrolyte solutions, or if unable to tolerate oral fluids or if severely dehydrated, intravenously with isotonic fluids. Oral rehydration therapy, in conjunction with educational programs on its effective use, allowed Peruvian physicians to achieve a survival rate of more than 99% in the more than 300,000 cholera patients seen during the first year of the outbreak in Peru.<sup>99</sup> Antibiotic therapy with tetracyclines and quinolones is effective in decreasing the duration and severity of the disease and in eradicating the infecting organism.<sup>100,101</sup>

Among the parasitic diseases capable of causing acute noninflammatory diarrhea, two coccidians are becoming increasingly important, especially because of the fact that water-borne outbreaks in the case of *Cryptosporidium parvum*<sup>102</sup> and food and water-borne outbreaks caused by *Cyclospora cayetanensis*<sup>9</sup> have been recognized with increasing frequency, and because both are capable of causing significant disease in immunocompromised hosts, particularly those suffering from AIDS.<sup>103,104</sup> The fact that chlorination is ineffective in eliminating these organisms adds to their impact.

Cryptosporidiosis can cause acute, noninflammatory, self-limited diarrhea. Although not limited to tropical areas, this parasite can be easily transmitted in areas with poor sanitation, with transmission rates similar to other highly infectious enteric pathogens such as *Shigella* species.<sup>105</sup> This coccidian parasite is particularly important in malnourished children and immunocompromised hosts, causing a more severe and prolonged clinical picture than in immunocompetent hosts. In a study in Guinea-Bissau, cryptosporidiosis was associated with excess mortality in children independent of malnutrition, socioeconomic factors, hygienic considerations, or breastfeeding.<sup>106</sup> *Cryptosporidium* has been found in as many as 50% of patients with AIDS and diarrhea in developing countries.<sup>107</sup> The diagnosis is made by the microscopic detection of oocysts in stools using acid-fast stains. Newer methods based on enzyme-linked immunosorbent assay (ELISA) or immunofluorescence are also available, and a recent study showed that all methods (including acid-fast staining) were equally sensitive and specific in detecting oocysts,<sup>108</sup> but the threshold of detection may not be optimal.<sup>109</sup> Therapy is problematic. Paromomycin has been shown to decrease oocyst excretion and the number of stools in patients with AIDS and cryptosporidiosis,<sup>110</sup> but is rarely curative. Recently approved for pediatric use in the United States, nitazoxanide was found to improve cryptosporidial diarrhea in one study of patients with AIDS in Mexico<sup>111</sup> and in HIV-negative children in Zambia.<sup>112</sup> The most effective intervention in this circumstance, however, remains immunologic recovery mediated by highly active antiretroviral therapy.<sup>113</sup>

*Cyclospora cayetanensis* has been described in Central and South America, the Caribbean, India, South Africa, Southeast Asia, eastern Europe, and recently from several outbreaks in the United States.<sup>9</sup> The disease seems to be endemic in areas of Nepal, Haiti, and Peru, and coincides with the rainy season in those areas. Although diarrhea is a common manifestation of *Cyclospora* infection, it may not be the presenting or predominant symptom in immunocompetent patients with this condition. A flulike syndrome may precede the onset of diarrhea. *Cyclospora* has been described as a cause of prolonged diarrhea in patients with HIV infection.<sup>104</sup>

The diagnosis of *Cyclospora* infection is based on the microscopic detection of oocysts from fecal specimens. Like *Cryptosporidium*, *Cyclospora* oocysts should be stained using acid-fast techniques such as the modified Ziehl-Neelsen stain or the Kinyoun acid-fast stain. *Cyclospora* oocysts are autofluorescent, appearing neon-blue when seen under an ultraviolet fluorescence microscope. Trimethoprim-sulfamethoxazole is the drug of choice for treating *Cyclospora* infection.<sup>114</sup>

In general, the management of acute, noninflammatory diarrhea in adults consists primarily of rehydration. If glucose or sucrose accompanies the isotonic fluid taken orally, the coupled absorption of sodium and water is often sufficient to replace fluid loss. In the absence of a significant febrile or inflammatory process, low doses of antimotility agents may offer some relief with minimum risk if cramping is severe. Symptomatic treatment is more often used in industrialized regions to improve symptoms, allowing persons to return to work or school. In tropical regions drugs play a minor role in the treatment of acute diarrhea. In selected cases, the use of antibiotics may provide a faster resolution of the symptoms.

### Gastroenteritis

The syndrome of acute nausea and vomiting, or “viral gastroenteritis” due to rotaviruses or noroviruses, commonly occurs in winter months in temperate climates, whereas this syndrome occurs year-round in tropical areas. The syndrome may also be caused by ingestion of preformed toxins of *Staphylococcus aureus* and *Bacillus cereus*. In a recent study from Taiwan, 20% and 15% of food-poisoning outbreaks were caused by *S. aureus* and *B. cereus*, respectively.<sup>115</sup>

Acute staphylococcal food poisoning typically occurs in food-borne epidemics. Patients will present initially with nausea, vomiting, and acute salivation, followed by abdominal cramps and diarrhea. The short incubation period (2 to 7 hours) and the existence of similar cases from a common source (meal) will suggest the diagnosis. The diarrhea usually is watery, but rarely can contain mucus and blood. Management consists of rehydration and monitoring and replacement of fluid and electrolyte losses. The symptoms usually resolve after a few hours. The potentially contaminated food should be examined for the presence of *S. aureus* (culture and Gram's stain) and enterotoxin. Meat, poultry, or their products (with ham and chicken most frequently implicated) are among the most common vehicles, but other foods, including fish and shellfish and milk and milk products, have also been implicated.<sup>116</sup>

Outbreaks of food-borne disease caused by *B. cereus* have been reported from tropical and nontropical areas. The organism produces an emetic or diarrheal syndrome induced by an emetic toxin and enterotoxin, respectively.<sup>117</sup> The emetic syndrome has a shorter incubation time (1 to 7 hours) and mimics staphylococcal food poisoning. Typically, the illness is associated with the ingestion of contaminated rice. The diarrheal syndrome has a longer incubation time (10 to 14 hours) and is usually related to the consumption of meat or vegetables. The diarrhea is profuse, lasting 12 to 24 hours, and is associated with abdominal pain, tenesmus, and nausea. *B. cereus* food-borne disease is self-limited, and again treatment is symptomatic, with rehydration provided as needed.

Many forms of diarrheal disease present with both watery diarrhea and vomiting. This form of gastroenteritis may be caused by enteropathogens that infect the upper gastrointestinal tract, including enteric viruses, bacterial pathogens such as diarrheogenic *E. coli*, *Shigella* spp., *Salmonella* spp., noncholera vibrios, *Campylobacter jejuni*, *Aeromonas* spp., and the protozoal parasites.

### Acute Inflammatory Diarrhea

Acute inflammatory diarrhea is characterized by the passage of many small-volume stools often containing blood and mucus. The causes of acute inflammatory diarrhea include several specific distal small bowel and colonic infections such as shigellosis, salmonellosis, campylobacteriosis, and amebiasis as the most representative organisms. Enteroinvasive *E. coli* has also been described as a cause of inflammatory diarrhea in tropical areas, but data on its prevalence are scarce.<sup>118,119</sup>

*Shigella* infection is characterized by the occurrence of an invasive bacterial colitis. It is estimated that *Shigella* spp. are responsible for over 163 million infections annually in developing countries, resulting in 1.1 million deaths.<sup>120</sup> The disease can present with acute bloody diarrhea with high fever and systemic manifestations of malaise, headache, and abdominal pain. The incubation period ranges from 8 hours to 9 days but is usually between 14 and 72 hours, and a very low inoculum is required for its transmission, facilitating its spread. This syndrome may be particularly severe in malnourished children, in whom the mortality can be as high as 11%.<sup>121</sup> *Campylobacter* enteritis has been associated with ingestion of contaminated water, raw milk, or poultry, and typically occurs in young children or in travelers visiting tropical areas, and it is recognized as a common pathogen during the rainy seasons.<sup>122</sup>

*Entamoeba histolytica* is an important cause of inflammatory diarrhea (although fecal leukocytes may be pyknotic or absent). It is estimated that infection by *E. histolytica* results in 50 million cases of invasive enteric disease and liver abscess and up to 100,000 deaths per year. High rates of infection occur in the Indian subcontinent, southern and western Africa, in the Far East, and in the tropical areas of Central and South America. Patients with amebic colitis typically present with a 1- to 2-week history of abdominal pain, tenesmus, and frequent loose watery stools containing blood and mucus. Fever can be present, and on occasion the disease can be severe enough to cause extensive colitis with colonic perforation.<sup>123</sup> The diagnosis of intestinal amebiasis is based on examination of the stools or biopsy of mucosal tissue. A direct saline wet mount will reveal motile trophozoites, some containing red blood cells, suggesting invasive disease. In 90% of the cases, three separate stool examinations are required for the diagnosis. Rapid stool antigen detection kits have been developed based on antilectin antibodies, differentiating between *E. histolytica* and the nonpathogenic *Entamoeba dispar* (which morphologically are indistinguishable) in stool specimens.<sup>124</sup> Metronidazole is the drug of choice for the treatment of invasive colitis. A luminal agent is recommended (usually iodoquinol) after nitroimidazole therapy of invasive amebiasis.

*Balantidium coli* is another protozoan capable of causing inflammatory diarrhea in tropical areas of the world.<sup>125</sup> The most common reservoir is swine, and in tropical

areas, monkeys. Like *E. histolytica*, this parasite invades the terminal ileum and colon, and may cause appendicitis or a dysenteric syndrome with rectosigmoid ulceration. The diagnosis is made by examination of wet preparations. Tetracycline is the drug of choice, but metronidazole is also active against this ciliated protozoan.<sup>126</sup>

In the management of patients with acute inflammatory diarrhea, it is necessary to perform a stool culture and a parasitologic examination, based on the organisms prevalent in each tropical area. Antimicrobials are essential to those with severe shigellosis and amebiasis, and empirical antimicrobial therapy is indicated in patients with diarrhea who have high fever and systemic toxicity or dysenteric disease.

### Persistent and Chronic Diarrhea

Most diarrheal episodes acquired in the tropics subside spontaneously within a few days, but in some patients diarrhea may persist for more than 2 weeks.<sup>127</sup> Classic causes of persistent diarrhea include *Giardia lamblia*, EAEC, and *Cryptosporidium* (which can also cause acute disease as described previously). *Cyclospora* can also cause persistent diarrhea.<sup>128</sup> Tuberculosis can also present with chronic diarrhea.<sup>70</sup>

Infection with *G. lamblia* ranges from asymptomatic cyst passage to a chronic syndrome of diarrhea with malabsorption and weight loss. Symptomatic giardiasis is characterized by the acute onset of diarrhea, abdominal cramps, bloating, and flatulence. Initially, stools may be profuse and watery, but later are commonly greasy and foul-smelling. Patients may present with periods of diarrhea alternating with periods of constipation or normal bowel habits, and the disease may wax and wane over months until therapy is given or spontaneous resolution occurs. For the diagnosis of giardiasis, repeated stool examinations may be necessary. Immunofluorescent- and ELISA-based methods have also been developed for the diagnosis of giardiasis. The drugs of choice for the treatment of giardiasis are metronidazole and tinidazole. Nitazoxanide, which is available as a liquid and given for 3 days, is another treatment option for children.

*Iso spor a belli* infection appears to occur more commonly in tropical and subtropical climates, and although diarrhea due to *I. belli* infection is typically acute and self-limited in the immunologically normal host, prolonged diarrhea can occur in certain patients.<sup>129</sup> In immunocompromised hosts, including patients with AIDS, isosporiasis can be protracted, with profuse diarrheal disease. Laboratory diagnosis is done by examination of stained stool specimens by the modified Ziehl-Neelsen method. *I. belli* infection responds promptly to trimethoprim-sulfamethoxazole therapy and recurrent disease can be prevented with either trimethoprim or sulfamethoxazole.

Among the nematodes, *Strongyloides stercoralis*, *Capillaria philippinensis*, *Trichuris trichiura*, and *Schistosoma* have been reported as causing diarrhea.<sup>130</sup> *Strongyloides* can be associated with persistent diarrhea, cramping abdominal pain, and weight loss, particularly when there is hyperinfection or disseminated strongyloidiasis. Eosinophilia is a prominent feature of this infection. Occasionally some patients may complain of nausea, vomiting, and weight loss with evidence of malabsorption or of protein-losing enteropathy.

*C. philippinensis* is a nematode that can also cause chronic diarrhea and malabsorption. The infection is seen in the Philippines and Thailand, and has also been reported in India and Egypt. *T. trichiura* can also be a cause of diarrhea (chronic dysentery) in highly parasitized patients. In schistosomiasis, diarrhea may occur due to the resulting granulomatous inflammation of the colon seen during the chronic phase in patients with heavy infections, or during acute schistosomiasis in unexposed patients (Katayama fever). In the latter case, the pathologic findings are completely different from those seen in the chronic form and are likely to be related to a hypersensitivity reaction.

Postinfective malabsorption (tropical sprue or "tropical enteropathy") was a common cause of chronic small bowel diarrhea, malabsorption, and weight loss in adults, especially in India, East Asia, and Central America. Small bowel bacterial overgrowth seems to play a role in the pathogenesis of tropical sprue. The treatment of tropical sprue with tetracycline and folate for up to 6 months seems to be most effective in symptom resolution and cure of diarrhea, with promotion of weight gain. *Tropical enteropathy* is a term used to describe an increasingly recognized syndrome of reduced absorption (with villous flattening) that is seen in many who live in tropical, developing areas (including Peace Corps volunteers)<sup>131</sup> and in many infections (ranging from *Cryptosporidium*, *Cyclospora*, or microsporidia to viral enteropathies).<sup>132</sup>

A form of persistent diarrhea showing worldwide distribution is Brainerd diarrhea. This is an idiopathic secretory process wherein the gut mucosa may show focal chronic inflammatory cells. The source is characteristically unpasteurized milk or untreated (well or surface) water. The prognosis is good, with diarrhea generally subsiding after 6 months to 1 year.

### Traveler's Diarrhea

Traveler's diarrhea is a syndrome characterized by a twofold or greater increase in the frequency of unformed bowel movements, associated with one or more signs or symptoms of enteric infection occurring during or shortly after a trip away from home. The tropical areas of Latin America, Africa, and southern Asia are considered the high-risk areas for traveler's diarrhea.<sup>133</sup> Attack rates are variable, but average approximately 40% for travel from an industrialized region to one of the high-risk areas.

Bacterial enteropathogens cause most cases of traveler's diarrhea regardless of the specific area of risk. Enterotoxigenic *E. coli* is the single most common bacterial pathogen isolated, followed by *Shigella* spp., *Campylobacter jejuni*, *Aeromonas* spp., *Plesiomonas shigelloides*, *Salmonella* spp., and noncholera vibrios. Parasites such as *G. lamblia* and *Cryptosporidium parvum* occur in approximately 2% to 3% of cases of traveler's diarrhea. In 20% to 50% of episodes of traveler's diarrhea, no agents can be identified despite complete microbiologic assessment. Most of this undefinable illness appears to be bacterial in origin in view of the favorable response to antimicrobial therapy.

The management of patients with traveler's diarrhea involves adequate rehydration, followed by dietary management and symptomatic treatment.<sup>94</sup> For rehydration, the consumption of potable fruit juices, caffeine-free soft drinks, or flavored mineral

water, coupled with a source of sodium chloride (e.g., saltines) is usually enough for hydrating most ill travelers. For adequate dietary management, staple foods such as cereals (wheat, rice, or oats), potatoes, noodles, crackers, and bananas are recommended during the acute phase of the illness. Patients should resume their usual diet once stools retain their shape. Drinks or food containing caffeine or lactose should be avoided while stools are unformed, since they may prolong diarrhea. Commonly used symptomatic drugs include bismuth subsalicylate and the antimotility synthetic opiate drugs such as loperamide. These agents are useful for the symptomatic treatment of mild to moderate cases of traveler's diarrhea.

Antimicrobial therapy shortens the duration of traveler's diarrhea from an average of 59 to 93 hours to 16 to 30 hours. This therapy is indicated in moderate to severe cases or when enteric symptoms persist for 48 hours or longer. Fluoroquinolones, or in South Asia, newer macrolides like azithromycin, are the preferred agents because of their activity against enteric pathogens in most high-risk parts of the world. Rifaximin, a poorly absorbed oral rifamycin derivative, was recently approved by the FDA for the treatment of traveler's diarrhea caused by noninvasive *E. coli*. Its use in patients with fever or blood in the stool and for those infected with *Campylobacter jejuni* is discouraged.

With regard to prevention, travelers to high-risk areas should be educated as to the safe foods and beverages to consume. Antimicrobial prophylaxis will prevent 70% to 80% of the disease that would occur without prophylaxis. If the traveler has an important underlying health impairment, or the trip will be ruined if the traveler has a brief illness that might force a change in itinerary, antimicrobial prophylaxis may be considered. An effective antibacterial drug for prevention of traveler's diarrhea is poorly absorbed rifaximin.<sup>135</sup> However, it is ineffective for treatment of invasive enteritis like Shigellosis. Bismuth subsalicylate has also been used as a prophylactic agent, preventing up to 65% of the cases of diarrhea that would occur during travel to high-risk areas if prophylaxis were not employed.<sup>136</sup> Travelers should begin taking the drug to be used for prophylaxis on their first day in the country they are visiting and should continue to take it for 1 or 2 days after leaving the country. However, pathogens such as *Cryptosporidium*, which may be devastating in immunocompromised patients, are prevented only by strict food and water precautions.

# Fever and Systemic Symptoms

MARY E. WILSON  
RICHARD D. PEARSON

## INTRODUCTION

Fever in the tropics and after travel is a common response to microbial invasion. Fever can presage rapidly progressive disease or indicate a trivial self-limited infection. Early symptoms of self-limited and lethal infections can be indistinguishable. Several features make evaluation of fever a major and continuing challenge: the causes include diverse infectious and noninfectious diseases; similar signs and symptoms characterize infections caused by unrelated pathogens requiring different interventions; and timing of onset of fever after exposure to a pathogen can range from hours to decades. Interventions may be lifesaving if applied in good time.

This chapter describes the causes of fever in persons with tropical and other diverse geographic exposures. The discussion focuses on recognizing possible causes of fever and on reaching a specific diagnosis and omits details of treatment, which can be found elsewhere in this book. Although the differential diagnosis for the febrile international traveler who has visited an area briefly and the febrile resident of the tropics may be similar, the relative likelihood of specific diseases and their consequences may differ greatly, thus mandating flexibility in the approach to the initial evaluation. Foreign-born residents of industrialized countries and their children who visit relatives and friends in developing countries may receive no pretravel prophylaxis and often have intense local exposures, placing them at greater risk for a wider range of infections than the usual vacationer or business traveler.<sup>1</sup> Several key concepts that underlie the evaluation of the febrile patient are listed in Box 124-1.

## PATHOGENESIS

The complex interactions of endogenous pyrogens and neural pathways in the pathogenesis of fever are reviewed in recent publications.<sup>2-4</sup> Pyrogenic cytokines, such as interleukin (IL)-1 $\beta$ , IL-6, and tumor necrosis factor- $\alpha$ , which result from stimulated mononuclear phagocytes, interact directly with the anterior hypothalamus, which coordinates thermoregulation through a hierarchy of neural structures. Prostaglandin E<sub>2</sub> is a proximal mediator in the preoptic-anterior hypothalamic area. Direct neural pathways from the periphery to the brain also may be involved.<sup>2</sup>

## Box 124-1 Key Concepts in the Evaluation of the Febrile Patient

- Fever after travel may be unrelated to exposures during travel.
- A history of fever in a person exposed to malaria should prompt evaluation for malaria, even if the patient is afebrile at the moment seen.
- Always look for malaria. Look again if exposures and clinical findings are consistent with that diagnosis.
- Exposure to many widely distributed infections is more common during travel than during life at home.
- Unfamiliar infections can follow exposures in temperate areas.
- Re-examine the febrile patient if the initial evaluation does not suggest a specific diagnosis.
- Keep in mind the public health implications. Should the infection be reported? Do contacts need treatment or special attention? Are special isolation techniques required?
- Use electronic networks to supplement and update information from other sources.

## EPIDEMIOLOGY

Fever is a common reason for seeking medical care during and after travel. Although risks and types of infection vary greatly depending on the circumstances of travel and the specific time and place, available studies provide general estimates of the likelihood of fever during and after travel. In the classic studies by Steffen and colleagues,<sup>5</sup> 152 of 7886 (almost 2%) of Swiss short-term travelers to developing countries reported "high fevers over several days" on questionnaires completed between 4 and almost 7 months after return from travel. Among those reporting fever, 39% said they had fevers only while abroad, 37% had fevers abroad and at home, and 24% had fevers at home only. In a study of 784 American travelers who spent 3 months or less in developing countries, 3% reported fever unassociated with other symptoms.<sup>6</sup> Among more than 20,000 ill returned travelers who were seen at 27 different clinical sites as part of the global GeoSentinel surveillance network, 22.2% had fever as a chief complaint.<sup>7</sup>

The risk of infection is strongly related to the geographic location of exposure. In recent years, risk of dengue was highest in parts of Asia, falciparum malaria in sub-Saharan Africa, and enteric fever in the Indian sub-continent. Among German travelers who acquired dengue fever in tropical areas in 2002, incidence rate per 100,000 travelers ranged from 27.9 for Thailand to 2.1 for the Greater Antilles islands in the Caribbean.<sup>8</sup> The snapshot of returning travelers is only part of the picture of the disease burden experienced by travelers. Many infections begin and are treated abroad. In one study that analyzed malaria in travelers to Africa, about half of the cases were treated abroad.<sup>9</sup> Activities of travelers and types of accommodations also influence risk. Studies by Steffen and co-workers<sup>10,11</sup> estimated the incidence rate of hepatitis A to be 3 to 6 per 1000 per month of stay in a developing country in unprotected travelers. The risk may rise to 20 per 1000 per month in persons living under poor hygienic conditions.

Useful information can be gathered from studies that have defined the causes of fever after travel. MacLean and colleagues<sup>12</sup> found malaria was the most common diagnosis (present in 32%)

in evaluation of 587 persons seen between 1981 and 1988 in Montreal with fever after tropical travel. In Switzerland, among 336 travelers and migrants who were seen at an outpatient clinic with a history of fever or malaise, 29% of those who had blood tested for malaria had confirmed malaria.<sup>13</sup> Of 195 consecutive patients hospitalized with fever between November 1992 and April 1993 at the London Hospital for Tropical Diseases, malaria was the most common diagnosis, accounting for 42% of admissions.<sup>14</sup> An additional two recent studies of hospitalized febrile returned travelers, one from Australia<sup>15</sup> and the other from Italy,<sup>16</sup> also found malaria as the most common diagnosis. Among 153 hospitalized febrile returned pediatric travelers in the UK, diarrheal disease and malaria were the most common diagnoses.<sup>17</sup> Recent papers also highlight the growing importance of dengue fever in tropical areas,<sup>18–20</sup> and as a cause of hospitalization after travel, second only to malaria in one series of patients seen in Israel.<sup>21</sup> It was the most common arboviral infection diagnosed in Swedish travelers in 1989 and 1990.<sup>22</sup>

It is worth noting that in the series of MacLean and associates<sup>12</sup> and Doherty and coworkers,<sup>14</sup> of the top 10 most common causes of fever after tropical travel, more than half are diseases with broad or worldwide distribution (respiratory infections, hepatitis, diarrheal illness, urinary tract infections, pharyngitis). Box 124-2 lists the most common causes of fever after tropical travel as described in published series. Many categories define a body site of infection and not a specific pathogen. In the series of MacLean and colleagues and Doherty and associates, the cause of about one fourth of the fevers was undefined. Among the patients with a specific etiologic agent defined, the most common were malaria, dengue, hepatitis A, rickettsial infection, streptococcal pharyngitis, typhoid fever, *Campylobacter*, *Salmonella*, *Shigella*, and amebic liver abscess.

Patterns of infectious disease are dynamic and will continue to change, influenced substantially by international travel and trade.<sup>23,24</sup> Several factors can lead to changes in the types and

relative frequencies of diseases diagnosed in persons visiting tropical regions: shifts in the epidemiology of disease; the rising resistance of infections to drugs; changes in popular destinations for travelers; the availability and wide use of effective preventive strategies (e.g., vaccines against hepatitis A and B); and new knowledge and techniques that facilitate diagnosis.

Studies that describe causes of fever in specific geographic areas help define the infectious disease profile for a region or country. They are most relevant to clinicians when the populations studied have included both local residents and visitors to that region. In the end, information about which infections occur and where is collected from anecdotal cases, published data on residents, and reports of outbreaks among travelers.<sup>25</sup> Often the available information is incomplete, unrepresentative, and out-of-date. The capacity to share information through electronic networks has improved the flow of information.<sup>26</sup> Regularly updated references,<sup>27–28</sup> Web sites, and tropical disease textbooks are good sources of information.

Exposures differ among travelers, long-term visitors (such as missionaries and Peace Corps workers), local residents, and military troops, but studies from these groups can be useful. Several studies looked at U.S. troops in Vietnam. The most frequently made diagnoses in 524 U.S. Marines in South Vietnam with acute fevers lasting at least 4 days included leptospirosis (20.1%), scrub typhus (11.6%), Japanese encephalitis (6.8%), and infectious mononucleosis (5.4%).<sup>29</sup> Another study in Vietnam of febrile American troops (with a negative malaria smear) found dengue the cause of fever in 29%, chikungunya in 9%, scrub typhus in 8%, and malaria in 7%.<sup>30</sup> While these studies provide a general idea of the pathogens in that region, most troops have a level of exposure to water, soil, and arthropods unmatched by the usual traveler (see Chapter 122).

Series of evaluations of febrile residents in other countries give some suggestion as to the heterogeneity of causes and geographic variation. For example, of 1629 febrile patients hospitalized in rural Malaysia, scrub typhus was the most common diagnosis (19.3% of all illnesses), followed by typhoid and paratyphoid fevers (7.4%), flavivirus infection (7.0%), leptospirosis (6.8%), and malaria (6.2%).<sup>31</sup> In Jakarta, Indonesia, in 1971–1972, bacteremic salmonella infections (predominantly *Salmonella enterica* serotype typhi) were the most common infections documented in patients hospitalized with fever.<sup>32</sup> In 876 consecutive febrile adults seen at a general hospital in Nepal in 2001, enteric fever and pneumonia were the most common clinical diagnoses.<sup>33</sup> A putative pathogen was identified in 37%, with the most common specific diagnoses being typhoid and paratyphoid fevers, murine typhus, pneumococcal infection, scrub typhus, and leptospirosis. The most common diagnoses in 505 adults in Spain with unexplained fever (with negative chest films and without localizing signs or symptoms) lasting 1 to 3 weeks were Q fever (21%), brucellosis (19%), spotted fever (murine typhus and boutonneuse fever; 15%), and mononucleosis syndrome (9%).<sup>34</sup>

In northern Thailand, melioidosis, caused by the gram-negative organism *Burkholderia pseudomallei*, is a major cause of community-acquired sepsis.<sup>35</sup> During a 1-year period from October 1986 through September 1987, 63 cases of septicemic melioidosis and 206 patients with other community-acquired septicemias were documented. Melioidosis accounted for about 20% of all documented cases of sepsis and about 40% of all deaths from community-acquired sepsis. As a cause of positive

Enteric fever  
Rickettsial infection  
Infectious mononucleosis  
Pharyngitis

\*Among the patients with a specific etiologic agent defined, the most common causes were malaria, dengue, hepatitis A, rickettsial infection, streptococcal pharyngitis, typhoid fever, *Campylobacter*, *Salmonella*, and *Shigella* infections, and amebic liver abscess.

Data from MacLean JD, Lalonde RG, Ward B: Fever From the Tropics, section 5. Travel Medicine Advisor. Atlanta, American Health Consultants, 1994, p 27.1; and Doherty JF, Grant AD, Bryceson AD: Fever as the presenting complaint of travelers returning from the tropics. Q J Med 88:277, 1995.

blood cultures, only *Escherichia coli*, *Staphylococcus aureus*, and *Pseudomonas aeruginosa* exceeded *B. pseudomallei*.<sup>36</sup> Melioidosis is also commonly reported in Malaysia.<sup>37</sup> Reflecting the importance of this pathogen, especially in Southeast Asia, melioidosis (see Chapter 34) is occasionally seen in travelers to and immigrants from these endemic regions.<sup>38,39</sup>

Serologic studies of local residents can provide insights into potential risks to persons who visit that region. A study that measured prevalences of antibodies reactive with *Coxiella burnetii*, *Rickettsia conorii*, and *Rickettsia typhi* in seven African countries found wide variations in evidence of past infections. The seroprevalence for *C. burnetii* was generally higher in areas of West Africa, where stock breeding is prominent; prevalences of antibodies reactive with *R. typhi* were higher in coastal regions.<sup>40</sup> In Inner Mongolia, nearly half of the human population tested had antibodies to *Rickettsia sibirica*.<sup>41</sup> Rates of positivity varied according to region with the highest rates being found in desert dwellers. Several reviews discuss the causes and evaluation of persons with fevers after visits to specific geographic regions: the Middle East,<sup>42,43</sup> Africa,<sup>44</sup> Southeast Asia and Oceania,<sup>45</sup> and Latin America and the Caribbean.<sup>46</sup> These are excellent sources of region-specific risks.

## APPROACH TO THE PATIENT WITH FEVER

Because unusual and unfamiliar infections occur in temperate regions as well as in the tropics, this discussion considers a wide range of possible exposures. Four questions can help focus thoughts on an individual patient with fever:

1. What is possible based on the geographic areas visited?
2. What is biologically plausible given the time of travel and incubation periods?
3. What are more likely diagnoses based on epidemiologic data, activities, host factors, and clinical and laboratory data?
4. What is treatable or transmissible or both?

Initial data will help set the tempo and scope for the workup. Often, therapeutic interventions are called for before a specific diagnosis can be confirmed.

## Time

Time can be a powerful tool in refining and limiting the list of diagnostic possibilities. Every pathogen can be characterized by a typical incubation period: the interval between exposure (entry into the host) and the development of clinical signs and symptoms of infection. Incubation periods can range from minutes to decades. Although the time range may be wide, most infections acquired by short-term travelers have incubation periods measured in days or weeks. In contrast, the time lapse between exposure and the first symptoms of filariasis in U.S. military personnel was between 5 and 18 months.<sup>47</sup> How long a pathogen can survive in the human host is relevant when thinking about how far back one must go when inquiring about past travel and exposures.

In the evaluation of a febrile patient with a recent travel history, it is useful to calculate the shortest and longest possible incubation periods, assuming potential exposure at all points during travel.<sup>48</sup> Sometimes this immediately allows the rejection of several diagnoses that had been considered. More complicated are patients who have had multiple, diverse geographic

exposures over many months or years, which vastly expands the number of diagnostic possibilities. Time analysis helps one construct a list of diseases in a geographic region that are biologically plausible given what is known about the usual ranges of incubation periods. Box 124-3 lists infections by interval between exposure and onset of symptoms. The clinician should always keep in mind that fever occurring after travel may not be related to exposures during travel. It is also useful to know the most typical time of symptom onset for infections whose incubation periods are characterized by a broad range, such as malaria. Among the cases of malaria reported to the Centers for Disease Control and Prevention (CDC)<sup>49</sup> in 2002, the dates of the person's arrival in the United States and onset of symptoms and the infecting *Plasmodium* spp were known for 681 cases. For 13.5% of cases, symptoms began before arrival in the United States. As can be seen in Table 124-1, 95% of cases of falciparum malaria became apparent before arrival or within the first month of arrival in the United States. In contrast, more than half of the cases of vivax malaria were not seen until more than a month after arrival and about 18% were seen more than 6 months after return. About 1% of all malaria cases had onset greater than 1 year after return. Similar findings come from a study of 482 cases of malaria from Canada in which 87% of cases of falciparum malaria presented within 6 weeks of return from travel, whereas one third of cases of vivax malaria presented more than 6 months after return.<sup>50</sup> The importance of malaria as a cause of late-onset fevers is underscored by the study by Antinori and associates.<sup>16</sup> Among 147 febrile hospitalized returned travelers, malaria was the diagnosis made in all cases of fever presenting more than 1 month after return from a tropical area (see Chapter 90).

Symptoms of dengue fever typically begin within 10 to 14 days of exposure. When fevers start 2 weeks or longer after exposure, dengue and most other arboviral infections are no longer biologically plausible. In contrast, among patients with acute schistosomiasis acquired during swimming in freshwater pools in the Dogon area of Mali, the median incubation period was 40 days (range, 14 to 63 days).<sup>51</sup> Other sequelae of schistosomiasis may appear later.<sup>52-57</sup>

## History

All stays in a given geographic region are not of similar relevance. Although many infections can be acquired through a single, brief encounter (the bite of an infective vector, ingestion of contaminated food, sexual contact, etc), the probability of an encounter that leads to disease increases with longer stays. For example, a study of British travelers to West Africa found that if the relative risk of malaria was considered to be 1 for a 1-week stay, it increased to 80.3 for stays that lasted between 6 and 12 months.<sup>58</sup>

The probability of exposure to uncommon infections also increases during a prolonged stay. Residence or extended stays in areas may also be more likely to be associated with greater exposure to local residents, rural or remote areas, and local foods and vectors. The separation between person and microbes that can be maintained during a brief visit while staying in a major city in a modern hotel seldom can be sustained over a period of months or years.

The type of residence and activities engaged in also affect the risk of infection. The initial history should review the

**Box 124-4** The History: Checklist of Potential Exposures

- When: season/month/year
- Duration of stay
- Area visited: urban or rural; altitude
- Living conditions: e.g., hotel with air conditioning or well-maintained screens, bed nets, camping
- Food and drink
  - Raw or undercooked meat or fish
  - Unpasteurized milk, cheese
- Activities
  - Close contact with others
  - Sex or other intimate contacts (dates, nature of sexual contact, with whom)
  - Crowded living and sleeping arrangements
  - Medical and other interventions
    - Injections, acupuncture, transfusions
    - Dental work, ear or body piercing
    - Tattoos
    - Shaved with used razor
  - Recreational or occupational
    - Water (swimming, wading, rafting, bathing in streams, etc)
    - Exploration of caves
    - Digging or soil contact
  - Animal exposure
    - Bites or licks to broken skin
    - Direct physical contact with dogs, birds, primates, etc
    - Proximity to birds, rodents

details of living conditions, work, and recreational activities en route and during the stay. Many travelers seek adventures during travels that make it likely they will come into contact with animals, insect vectors, and soil- and water-related pathogens. Of 32 Dutch travelers who were found to have leptospirosis, a history of contact with surface water could be confirmed in all but one case.<sup>59</sup>

Some infections, such as louse-borne relapsing fever<sup>60</sup> and Chagas' disease,<sup>61</sup> pose little risk to most short-term travelers because their living conditions are unlikely to lead to exposure. Although hantaviruses are widely distributed, most travelers have little risk of exposure. In studies of hemorrhagic fever with renal syndrome in two villages in China, risk factors for infection included direct rodent contact, camping in grain fields, living in a house on the periphery of a village, and some kinds of agricultural work—activities that few visitors to a region would engage in.<sup>62</sup> Acquisition of plague during travel has been an exceptional event.<sup>63</sup>

Box 124-4 lists elements of the history that may provide clues to specific exposures. Sources of infection are typically food or beverages, close contact with other persons, or exposure to pathogens in soil and water or pathogens carried by vectors or animal hosts. Although the list is not exhaustive, it indicates the types of exposures that may be relevant. Table 124-2 lists specific infections that can follow various types of exposures.

Casual sex with a new partner is common during travel, occurring in 5% to 50% of travelers.<sup>64–67</sup> This information may not be offered unless the patient is asked specifically about sexual exposures. A study by Correia and colleagues found that 15% of Canadians traveling internationally reported sex with a new partner or potential exposure to blood and body fluids through other means (e.g., injections, tattoos, dental work, other skin-perforating procedures).<sup>68</sup> Of 782 persons who were seen at the Hospital for Tropical Diseases over a 6-month period in 1991 and 1992, 97% agreed to participate in a study of sexual behavior. During their most recent trips abroad 18.6% of travelers reported a new sexual partner, almost two thirds of those did not use condoms consistently, and 5.7% acquired a sexually transmitted disease (STD) during the most recent trip.<sup>69</sup>

Many infections exhibit striking seasonality in patterns. The risk may be absent during parts of the year for some vector-borne infections, especially if there are distinct rainy

**Table 124-2** Examples of Infections Associated with Specific Exposures

Contacts	Infection
Sex, blood, body fluids	Hepatitis A, B, C, D; CMV, HIV, syphilis
Freshwater	Leptospirosis, schistosomiasis
Rodents and their excreta	Hantaviruses, Lassa fever and other hemorrhagic fevers, plague, rat-bite fever, murine typhus
Soil	Several fungi, melioidosis
Animals and their products	Q fever, brucellosis, anthrax, plague, tularemia, toxoplasmosis, rabies, psittacosis
Ingestions	
Unpasteurized milk and products	Brucellosis, salmonellosis, tuberculosis, Q fever.
Raw or undercooked shellfish	Clonorchiasis, paragonimiasis, vibrios, hepatitis A
Raw or undercooked animal flesh	Trichinellosis, salmonellosis, <i>Escherichia coli</i> O157, campylobacteriosis, toxoplasmosis
Raw vegetables, water plants	Fascioliasis
Arthropod vectors	
Mosquitoes	Malaria, dengue, filariasis, yellow fever, Japanese encephalitis, many other arboviral infections
Fleas	Typhus (and exposure to flea feces), plague
Lice	Relapsing fever, epidemic typhus, trench fever
Sandflies	Leishmaniasis, sandfly fever
Black flies	Onchocerciasis
Triatomine bugs (reduviid bugs)	American trypanosomiasis (Chagas' disease)
Tsetse flies	African trypanosomiasis
Ticks or mites	Babesiosis, Crimean-Congo hemorrhagic fever, ehrlichiosis, Kyasanur Forest disease, Lyme disease, scrub typhus, spotted fevers (rickettsial), tick-borne encephalitis, tularemia

and dry seasons or the climate is temperate and the winters cold. Risk of dengue fever in German travelers to Thailand showed a marked seasonal pattern. Incidence per 100,000 travelers varied from 2 in January 2002 to more than 70 in April.<sup>8</sup> Infections that are spread from person to person (e.g., influenza) and those associated with soil and water (e.g., melioidosis) can also show a seasonal pattern. Influenza epidemics typically occur in winter months in temperate regions. They can occur throughout the year in tropical areas, although epidemics often follow changes in weather patterns (e.g., monsoons). Melioidosis occurs more often in the rainy season,<sup>70</sup> meningococcal meningitis in Africa in the dry season,<sup>71</sup> and leptospirosis during warmer months in temperate areas and during the rainy season in the tropics.<sup>72</sup>

## Host Factors

Host factors can affect the probability of exposure, the likelihood of infection if exposure occurs, and the expression or outcome of infection. Hepatitis A, for example, is often mild or clinically inapparent in a young child, whereas it causes serious illness and, rarely, death in the older adult. Many persons who have grown up in a developing country are immune to hepatitis A, though they may be unaware of having had hepatitis. Prior immunizations and chemoprophylactic agents also influence the probability of disease and delay the onset of symptoms or alter clinical expression.<sup>73</sup> A study in the United Kingdom found that persons taking mefloquine had delayed onset of symptoms of falciparum malaria.<sup>74</sup> A history of having received a vaccine or having taken prophylaxis for a specific disease should not lead one to automatically exclude the possibility of that disease. Rather, one must consider the efficacy of the vaccine in the individual host, compliance with prophylactic regimens, and local drug resistance patterns at the time of the intervention.<sup>75</sup> Preventive measures vary greatly in efficacy. Failures with yellow fever vaccine have been reported only rarely,<sup>76</sup> whereas protective efficacy with the parenteral Vi capsular polysaccharide typhoid vaccine is estimated to be 60% to 72% in field trials in endemic regions (Nepal and South Africa).<sup>77,78</sup> Typhoid and paratyphoid fever have been reported in visitors to Nepal, including those who received typhoid vaccination.<sup>79,80</sup> A single dose of measles vaccine is about 95% efficacious in preventing measles in preschool-aged children immunized at or after 15 months of age.<sup>81</sup> The protective efficacy of influenza vaccine depends on host factors as well as whether antigens included in the yearly formulated vaccine match the circulating influenza viruses. A complete history should include dates and types of vaccines received. Potentially relevant host factors are listed in Box 124-5.

Malaria chemoprophylaxis can fail because of missed doses and resistant parasites, but even when prophylactic regimens are followed compulsively, breakthrough cases of malaria still occur. Malaria should not be rejected as a possible diagnosis just because a patient has taken prophylaxis.<sup>82</sup> Efficacy can vary depending on the drug regimen used, the geographic region, and time. Drugs that were effective in the past may no longer work because of increasing resistance of malaria parasites. Commonly used chemoprophylactic agents act on the blood stage of the parasite, hence do not protect against relapses due to *Plasmodium vivax* and *Plasmodium ovale*. In a study of

delayed-onset malaria (defined as >2 months after return), approximately two thirds of patients with vivax or ovale malaria reported taking antimalarials active against the blood stage.<sup>83</sup> If travelers take drugs acquired locally in a developing country, counterfeit or substandard drug is a possible reason for failure of treatment or prophylaxis.<sup>84,85</sup> Doxycycline, one option for chemoprophylaxis for malaria, reduces the risk of certain other infections or may modify the clinical course. Doxycycline has demonstrated efficacy in preventing leptospirosis<sup>86</sup> and has been used to prevent traveler's diarrhea, although resistance among enteric bacterial pathogens is now widespread. Among other infections that might be prevented or altered are rickettsial infections, relapsing fever, syphilis, and plague. Of note, poor response of scrub typhus (*Orientia tsutsugamushi*) to doxycycline has been reported from Thailand, where rifampin worked better.<sup>87</sup>

A complete list of other drugs the patient is taking or has recently used should be reviewed. This should include herbal or traditional remedies and medications obtained without prescription, including injections. Many drugs, including antimicrobials, can be purchased without a prescription in many parts of the world. Recent drug use can influence the likelihood of susceptibility to infections, resistance patterns of infecting organisms, and the results of diagnostic tests and can also be associated with side effects and adverse reactions. Drug fever<sup>88</sup> and cutaneous reactions can mimic infections or complicate their evaluation if both a drug reaction and infection overlap in time. Antipyretics and anti-inflammatory agents may mask fever and local symptoms.

Underlying diseases or conditions may predispose to infections or influence their severity. Persons who have lost gastric acid because of surgery, H<sub>2</sub> blockers and other drugs, or disease may be more likely to become infected with some pathogens that enter through the gastrointestinal tract. The interaction with human immunodeficiency virus (HIV) and a number of infections is discussed in the following sections.

Genetic factors affect susceptibility to and expression of infections. A prominent example is malaria. Persons whose erythrocytes are Duffy antigen-negative cannot be infected with *P. vivax*. Falciparum malaria is less severe in persons who are heterozygous for sickle cell hemoglobin.<sup>89</sup> Some persons may be genetically resistant to infection with parvovirus.<sup>90</sup> In most instances, genetic determinants are not yet sufficiently well characterized to influence the approach to the patient with fever.

## CLINICAL MANIFESTATIONS

### Duration and Pattern of Fever

Many textbooks have dedicated long discussions to the diagnostic implications of different patterns of fever. In an era when few patients are hospitalized and monitored regularly with vital signs, little information may exist about their fever patterns. General characteristics of fever that may provide some discriminatory value include onset (abrupt vs. gradual), height (very high vs. low), pattern (e.g., continuous, every 48 hours, biphasic, intermittent), and duration. These characteristics may point the clinician to some infections that are more and others that are less likely but should not be interpreted rigidly.<sup>91,92</sup> Few patients with malaria, for example, follow the textbook pattern of fevers. Patients with malaria are frequently afebrile at the time of their first visit, though offering a history of fever or chills. In a study of 482 patients with malaria in Canada, only one half had fever at the time of presentation.<sup>50</sup> Of those with fever and malaria (nonimmune travelers), fewer than 50% had the classic synchronous pattern. In a smaller study of 86 patients with malaria, 22 (25%) were afebrile at the initial hospital visit.<sup>93</sup> Absence of fever and systemic toxicity should not deter the clinician from seeking evidence of malaria in the patient with an appropriate exposure history. In some instances patients with fever are unaware of having fever. Self-treatment with antipyretics and antimicrobials can change the natural pattern of fevers.

### Undifferentiated Fever

Many infections first manifest with fever and no other signs or symptoms, or only nonspecific associated symptoms such as headache and malaise. With time, focal findings or other clues often emerge, but early interventions may be necessary to prevent serious sequelae or death. When tropical exposures have occurred within the past month, the list of possible diagnoses is long.<sup>94</sup> In general, the most common diagnoses in returned travelers with undifferentiated fever are malaria, dengue, rickettsial infections, leptospirosis, enteric fever, and common infections with a global distribution, such as respiratory and urinary tract infections. The fungal infections histoplasmosis and coccidioidomycosis, which have caused outbreaks in travelers, can begin with a nonspecific acute febrile illness. The presence of polymorphonuclear leukocytosis should lead to studies for bacterial sepsis with common organisms, such as staphylococci, meningococci,<sup>95</sup> streptococci, and other pyogenic organisms. *Campylobacter* infections, Legionnaires' disease, and tularemia<sup>96</sup> may begin with undifferentiated fever and an elevated white blood cell (WBC) count. Leptospirosis,<sup>72,97,98</sup> tick-borne relapsing fever,<sup>99</sup> louse-borne relapsing fever,<sup>100,101</sup> and amebic liver abscess<sup>102,103</sup> often cause elevation of the WBC count. The total WBC count is often normal or low in some bacterial infections such as typhoid fever (unless complicated by intestinal perforation),<sup>104–108</sup> brucellosis,<sup>109,110</sup> rickettsial infections,<sup>111–121</sup> ehrlichiosis,<sup>122</sup> Q fever,<sup>123–125</sup> many protozoan infections (e.g., malaria, toxoplasmosis, visceral leishmaniasis), and many viral infections (dengue, HIV, chikungunya,<sup>126</sup> Lassa, cytomegalovirus [CMV], Epstein-Barr virus [EBV], and many others). The initial evaluation should include a WBC and differential leukocyte count. The presence of large numbers of atypical lymphocytes

or high-grade eosinophilia would shift more attention toward viral and helminthic infections, respectively. A marked left shift can be seen early in many infections (e.g., dengue) which later may be characterized by lymphocytosis.

Among the acute undifferentiated (at least initially) fevers that benefit from specific treatment are bacterial (including rickettsial and spirochetal infections), viral (e.g., Lassa fever), and protozoan (e.g., malaria, amebiasis, African trypanosomiasis) and several fungal infections.

As mentioned previously, sexual contacts are common during travel, and several sexually transmitted infections, including primary HIV infection,<sup>127–129</sup> CMV, syphilis, and hepatitis B,<sup>130</sup> can present with undifferentiated fever.

Among the rare but “cannot miss” diseases are plague, Lassa fever,<sup>131</sup> anthrax,<sup>132,133</sup> African trypanosomiasis,<sup>134–137</sup> and rabies. In each instance, early recognition can lead to appropriate treatment, isolation, or public health interventions.

## ASSOCIATED SYMPTOMS AND CLINICAL FINDINGS

The presence of hypotension, tachypnea, confusion or altered mental status, and evidence of hemorrhage demand urgent evaluation and intervention.

### Fever and Hemorrhage

Among the infections that evoke greatest fear are the so-called hemorrhagic fevers. The term describes the shared clinical manifestations, not a specific cause. The globally distributed *Neisseria meningitidis* is a cause of acute hemorrhagic fever. Other acute bacterial infections (e.g., leptospirosis, plague, rickettsial infections, vibrio infections), rarely fungi, and other processes can occasionally cause a similar clinical picture. Among travelers, the list of potential causes is vastly expanded and includes some infections for which specific treatment can be lifesaving and others for which only supportive therapy is available but also may save lives. The viruses associated with hemorrhagic fevers include dengue virus,<sup>138</sup> hantaviruses,<sup>139</sup> Lassa fever,<sup>140</sup> Ebola,<sup>141</sup> Marburg, Rift Valley,<sup>142</sup> Venezuelan hemorrhagic fever,<sup>143</sup> yellow fever,<sup>144</sup> Crimean-Congo hemorrhagic fever viruses,<sup>145</sup> and others.<sup>146,147</sup>

Viruses typically associated with hemorrhagic fever are listed in Table 124-3 along with their known geographic distributions.<sup>146–148</sup> Acquisition most often involves the bite of an infective vector (usually a mosquito or tick) or contact with rodents or their excreta. Because some viral hemorrhagic fevers are treatable (e.g., Lassa fever<sup>149,150</sup> and possibly Crimean-Congo hemorrhagic fever<sup>151,152</sup> and findings from some bacterial infections (e.g., meningococcemia, leptospirosis) can cause similar hemorrhagic manifestations, it is essential to proceed rapidly with the initial evaluation. Management should always include general support, even when specific treatment is not available. Infection control measures that include masks, gloves, gowns, and appropriate protocols for handling specimens should be used in the initial care of a patient with hemorrhagic fever that may have been acquired in a tropical area, pending more complete information, to protect members of health care and laboratory teams.<sup>150</sup> If infections that can be spread from person to person (e.g., Lassa fever, Ebola, Crimean-Congo hemorrhagic fever, Marburg,

Venezuelan and Argentine hemorrhagic fever viruses) are among those that are plausible based on time and place of exposures, it makes good sense to request input early from public health officials and the CDC or other experts in the field who can advise about the handling of the patient and clinical specimens and can also expedite diagnostic studies. Staff at the Special Pathogens Branch, Division of Viral and Rickettsial Diseases, CDC, can provide information and assistance. In some instances, prompt recognition of an unusual infection may make it easier to trace contacts and prevent or limit future cases.

Endemic hantaviruses vary with geographic region. The clinical manifestations of infection also vary widely and include severe hemorrhagic fever with renal syndrome, hantavirus pulmonary syndrome (with a mortality rate of about 50%), and a milder illness, nephropathia epidemica,<sup>153</sup> found in Scandinavia.<sup>154</sup>

### Fever and Central Nervous System Findings

The presence of altered mental status, stiff neck, or focal neurologic signs in a patient with fever heralds a range of infections, including many that can result in serious sequelae or death. Neurologic findings can be useful in helping focus the

workup but also suggest that the workup should proceed rapidly. High fever alone or metabolic derangements associated with serious systemic infections can lead to an altered mental status in the absence of central nervous system (CNS) invasion. Patients with Legionnaires' disease, for example, may be lethargic and confused even though the cerebrospinal fluid (CSF) may be acellular and sterile. Headaches, sometimes severe, may accompany systemic infections such as malaria, rickettsial infections, dengue, and typhoid fever. It may be necessary to image the CNS and sample spinal fluid to assess CNS signs and symptoms. Common infections with a worldwide distribution, such as meningococcal infections, syphilis, tuberculosis, herpes simplex, and *Cryptococcus* infections, should always be considered and sought, as appropriate.

In travelers, pathogens that may invade the CNS include bacteria, viruses, fungi, helminths, and protozoa, though bacteria and viruses predominate. Many geographically focal arthropod-borne viruses cause meningitis or encephalitis. Among those that threaten travelers is Japanese encephalitis (JE), the mosquito-borne flavivirus widely distributed in Asia and also found in northern Australia.<sup>155</sup> Imported cases of JE are reported but rare.<sup>156</sup> Other flaviviruses that cause encephalitis include West Nile (wide distribution now includes the Americas), St. Louis encephalitis (North, Central, and South America), and Murray Valley (Australia and New Guinea). Dengue fever can manifest with neurologic findings, including encephalitis and transverse myelitis, but neurologic presentations are noted in 1% or less of cases.<sup>157</sup> JE virus, as well as West Nile virus and Murray Valley virus can cause a poliomyelitis-like illness.<sup>158</sup> In general, effective therapies for these infections have not yet been identified, though supportive care may improve the outcome. Rabies is another cause of encephalitis occasionally acquired in developing areas of the world where dog rabies remains a persistent threat.

Nipah virus, a paramyxovirus, has been identified as a cause of severe, rapidly progressive encephalitis in Malaysia and Singapore in outbreaks first noted in 1998.<sup>159</sup> Since 2001, outbreaks have occurred in Bangladesh, with probable person-to-person transmission.<sup>160</sup> To date, cases have not been reported in travelers, and initial outbreaks affected persons having close contact with pigs.

Sandfly fever viruses are occasional causes of fever and headache in travelers to Mediterranean countries and elsewhere.<sup>161–164</sup> Fever and headache are common findings; some serotypes, including the Toscana serotype, have been associated with meningitis or meningoencephalitis and prolonged convalescence.<sup>164</sup> Of eight German tourists diagnosed with acute sandfly virus infection, serotype Toscana, seven acquired infections during visits to Tuscany (Italy) and one to Portugal.

In patients who have visited areas of Africa endemic for African trypanosomiasis (sleeping sickness),<sup>165–169</sup> early diagnosis and treatment of infection can prevent CNS involvement, which complicates therapy and worsens prognosis. Patients with African trypanosomiasis must be evaluated for possible CNS infection, since its presence will alter management. Other treatable infections that can involve the CNS and may be unfamiliar to many clinicians include Q fever,<sup>170</sup> rickettsial infections, relapsing fever, brucellosis, leptospirosis,<sup>98</sup> and bartonellosis. Anthrax and plague, both rare, can cause hemorrhagic meningitis. In patients with cerebral malaria, parasites may be present in small numbers on initial peripheral smears.<sup>171</sup> CNS manifestations occur in about 20% of patients

with ehrlichiosis caused by *Ehrlichia chaffeensis* and include altered mental status, lymphocytic pleocytosis, and elevated CSF protein.<sup>172</sup> Many clinicians are familiar with Lyme disease and ehrlichiosis but may be unaware that they occur in many countries outside the United States.<sup>173,174</sup>

Few helminthic infections cause fever and neurologic findings. The presence of eosinophilia should suggest one of these infections (see Chapter 125). Angiostrongyliasis due to *Parastrongylus* (*Angiostrongylus*) *cantonensis* can cause fever, headache, and eosinophilia in CSF and peripheral blood. In 2000, an outbreak of eosinophilic meningitis occurred in travelers who had visited Jamaica and had shared a meal.<sup>175</sup> Disseminated strongyloidiasis in compromised hosts can be associated with bacteremias and meningitis, sometimes years or decades after the host has left the endemic region. Other helminths that reach the CNS (e.g., cysticercosis) are not associated with an acute febrile illness. When trichinellosis<sup>176</sup> and schistosomiasis cause fever and CNS findings, it is typically in the setting of other systemic findings, including eosinophilia.

The differential diagnosis of a patient with fever and unexplained meningitis should include the possibility of drug-induced meningitis. Among the drugs that have been implicated are trimethoprim-sulfamethoxazole (TMP-SMX) and several nonsteroidal anti-inflammatory agents, drugs that are used widely and may be obtained without a prescription in many parts of the world.

### Fever and Respiratory Symptoms

The respiratory tract is a common site of infection during and after travel, though the specific cause often remains undefined.<sup>6</sup> Among approximately 22,000 ill returned travelers who presented to a GeoSentinel site for medical evaluation (from September 1997 through August 2001), almost 8% had respiratory tract infections.<sup>177</sup> In a study of American travelers,<sup>6</sup> 26% reported respiratory tract symptoms during travel and 10% following travel. Patients with pneumonia after travel should be evaluated for common pathogens, such as *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Haemophilus influenzae*, and *Mycoplasma pneumoniae*. Outbreaks and sporadic cases of influenza occur in travelers, including on cruise ships<sup>178</sup> and in pilgrims to the Hajj.<sup>179</sup> One well-studied outbreak documented the spread of influenza on an aircraft.<sup>180</sup> Recent outbreaks of avian influenza in Asia have heightened worries that a highly pathogenic strain could become more transmissible in humans.<sup>181</sup> Probable person-to-person transmission was noted in Thailand in 2004.<sup>182</sup> The clinical spectrum may include diarrhea and CNS changes.<sup>183</sup> Outbreaks of SARS in 2002–2003 caused more than 8000 cases and almost 800 deaths and disrupted global travel.<sup>184</sup> Fever is prominent in SARS, often preceding the development of respiratory findings. Transmission also occurred on aircraft.<sup>185</sup> Several clusters have highlighted the acquisition of Legionnaires' disease during travel in many regions of the world.<sup>186,187</sup> Between 45% and 65% of cases of Legionnaires' disease in England and Wales have been travel-related.

Melioidosis is a common cause of pneumonia, especially in parts of Asia, as described previously. The fungal infections coccidioidomycosis and histoplasmosis have caused recent outbreaks in travelers in the Americas.<sup>188–190</sup> Q fever is a common cause of pneumonia in some areas, including Spain.<sup>34</sup>

Risk of infection with *Mycobacterium tuberculosis* is increased by travel to areas highly endemic for tuberculosis, especially with prolonged stays.<sup>191,192</sup> Transmission can also occur on long flights. Infection may manifest months or years after travel.

Other infections that can produce prominent pulmonary findings include hantaviruses, plague, tularemia, and anthrax. In patients with amebic liver abscess, extension of the process to the diaphragmatic surface of the liver may cause pulmonary findings.<sup>102</sup> Severe malaria may be complicated by acute respiratory distress syndrome. Pulmonary infiltrates may be present during the pulmonary migration phase of several helminths, including hookworm, ascaris, and strongyloides (see Chapter 125). Acute schistosomiasis (Katayama syndrome) may cause fever and pulmonary infiltrates.<sup>193</sup> Pulmonary emboli and infarction can cause fever and pulmonary findings that can mimic respiratory infections including pneumonia.

### Fever and Diarrhea

Many infections are acquired via ingestion of contaminated food or drink. The gastrointestinal tract may be the portal of entry and the initial or primary site of infection. Enteric infections, such as campylobacteriosis and salmonellosis, may produce an illness with just fever and no, few, or delayed gastrointestinal symptoms. Workup of the febrile patient with diarrhea should include studies for *Clostridium difficile*. This infection has been reported after many antimicrobials, including doxycycline taken for malaria chemoprophylaxis.<sup>194</sup> Diarrhea and other gastrointestinal symptoms can also be found as part of systemic infections (e.g., malaria, dengue fever, rickettsial infections), hence the workup of the febrile patient with diarrhea should not focus exclusively on enteric pathogens. Persons with an amebic liver abscess may give a history of diarrhea, but many deny diarrhea at the time they seek medical care for fevers. In a series of 52 patients with amebic liver abscess in Cairo, 25% gave a history of diarrhea and 6% reported dysentery.<sup>195</sup> Fever and right upper quadrant pain were the most common manifestations. In this series, 42% had an acute illness, characterized by high fever, vomiting, and leukocytosis, and 58% had a more chronic illness, often with low-grade fever, weight loss, and anemia.<sup>195</sup>

Systemic infections can involve the gut and be associated with gastrointestinal symptoms and fever. Some of these include visceral leishmaniasis, histoplasmosis, tuberculosis, nontuberculous mycobacteria, and Whipple's disease.<sup>196</sup>

### Fever and Hepatitis

Hepatitis A traditionally has been the most common form of hepatitis after travel to developing countries. In Swedish travelers who did not receive immunoglobulin in a study that was done before hepatitis A vaccine was available, the risk of hepatitis A was 1 in 100 to 150 after travel to tropical Asia or Africa.<sup>197</sup> Hepatitis A is extremely uncommon in persons who have recently received immunoglobulin. Available studies with the hepatitis A vaccines suggest a protective efficacy of greater than 95%. A relapsing form of hepatitis A has been described, though fever has not been a prominent finding.<sup>198,199</sup> Hepatitis B assumes a more important role in persons with prolonged stays in developing areas and those who have close contact, including sexual contact, with local residents, receive injections, or have other parenteral exposures.<sup>200</sup>

Among American troops in Korea (1983 to 1985) hospitalized with acute hepatitis, 75% had hepatitis B and 25% had hepatitis A. Immunoglobulin was used, but hepatitis B vaccine was not available at the time the study was done. Serologic studies suggested that 6% of American troops stationed in Korea for 4 to 12 months became infected with hepatitis B. Among those with acute hepatitis B, 83% gave a history of Korean sexual partners.<sup>130</sup>

Hepatitis D virus (HDV) infection, which requires a helper function from hepatitis B virus (HBV), is a risk for persons already infected with HBV or who become coinfecting with HBV and HDV. Hepatitis D can be expressed in the absence of detectable hepatitis B surface antigen (HBsAg).<sup>201</sup> Acute infection can be confused with yellow fever in tropical regions where both can occur. HDV has been a cause of severe and frequently fulminant hepatitis in outbreaks in South America (Amazon Basin).<sup>202</sup> Other geographic areas reported to have a high incidence of infection include parts of Africa, the Middle East, and islands of the South Pacific.<sup>203</sup> Rates of hepatitis D infection in HBsAg carriers range from 30% to 90% in these areas. In Europe, high rates of infection have been reported primarily in the Mediterranean basin, the Balkan peninsula, and in the European part of the former Soviet Union. In North America, Australia, and other parts of Europe, hepatitis D is largely a problem in intravenous drug users.

Travelers occasionally acquire hepatitis E.<sup>204–206</sup> Outbreaks have occurred in many areas, including Mexico, Asia,<sup>204–207</sup> and Africa. The manifestations of HEV are similar to those of HAV except in pregnant women, who are at substantial risk of developing severe or fulminant hepatitis with HEV.

Of 328 North American missionaries, 78% of whom served in sub-Saharan Africa, 5.8% seroconverted showing evidence of infection with hepatitis A, 8.5% with hepatitis B, 0.6% with hepatitis C, and 0% with hepatitis E viruses. The study period was between 1967 and 1984. Their average period of service was 7.3 years.<sup>208</sup>

In the evaluation of patients with fever and marked abnormalities of liver function, treatable infections such as leptospirosis, Q fever, brucellosis, and rickettsial diseases should be considered. Many viral infections, including yellow fever, cause prominent hepatic dysfunction.

## Fever and Rash

Skin findings are visible clues that may help suggest or exclude specific diagnoses<sup>209–211</sup> (see also Chapter 126). The distribution of a rash, the nature of the lesions, the time of onset relative to other symptoms, and its evolution over time may be helpful pieces of information. The astute clinician will repeat careful examinations of the skin when a patient has persistent fever of uncertain cause. Rashes are not a clinical feature of malaria; thus, the presence of a rash excludes malaria as the cause of fever unless the patient has a rash for another reason. A careful history of drugs, including over-the-counter agents, is essential in any patient with a rash. Skin lesions secondary to insect bites, hypersensitivity reactions to topical agents, and dermatitis related to water-associated infestations may occur in patients with an acute systemic infection causing fever. The presence of skin lesions from an unrelated process can sometimes misdirect the initial evaluation to focus only on infections that cause skin lesions.

Petechial lesions and hemorrhagic findings herald life-threatening diseases and should prompt a search for one of the hemorrhagic fevers (see previous discussion). Initial skin lesions in these infections may not be hemorrhagic. In the series of patients with African tick-bite fever described by Raoult and coworkers, 4% of patients with rash had purpuric lesions.<sup>114</sup> A local skin lesion may reflect the portal of entry of the pathogen, for example, tache noire in rickettsial infection, erythema migrans, cutaneous diphtheria, the eschar of anthrax, chagoma in American trypanosomiasis (Chagas' disease), and the chancre in African trypanosomiasis.<sup>212</sup> Diffuse rashes are seen in many bacterial (including rickettsial) and viral infections. Few are sufficiently distinctive to allow a definitive diagnosis on the basis of the skin findings alone. Characteristic skin lesions, such as those described in many rickettsial infections and the rose spots of typhoid fever, may appear late or not at all.<sup>213</sup> Their absence should not lead the clinician to reject the diagnosis if findings are otherwise typical. Rashes that mimic the diffuse erythema of staphylococcal and streptococcal toxic shock syndrome have been reported in other infections, such as dengue fever and ehrlichiosis. Rubella and measles viruses remain endemic in many countries, and these infections can be acquired during travel.<sup>214</sup>

Among the more common infections causing high fevers after tropical exposures, dengue produces a rash in 30% to 50% of cases,<sup>215,216</sup> typhoid fever is associated with rose spots (though they may be evanescent) in 30% to 50%, and the rashes of rickettsial infections vary with the infecting rickettsial species. Ross River fever, also known as epidemic polyarthritis and found in South Pacific islands and Australia, is associated with a maculopapular rash in 40% to 78% of cases.<sup>217,219</sup> Although dengue has become increasingly recognized as a common infection in travelers, all that resembles dengue is not dengue. During a 1984 dengue outbreak in Mexico, Bustos and colleagues<sup>220</sup> found that 10% of patients with the clinical diagnosis of dengue had serologic evidence of acute rubella infection. Rickettsial infections can also mimic dengue fever. During a 1993 study of dengue fever in Mexico, 50 patients with clinical findings suggestive of dengue fever but negative serologic tests for dengue infection underwent further study. Twenty (40%) had IgM antibodies reactive with spotted fever group rickettsiosis.<sup>221</sup> Other treatable infections that can cause skin lesions include leptospirosis, relapsing fever, rat-bite fever, syphilis, Q fever, psittacosis, bartonellosis,<sup>222</sup> brucellosis,<sup>223</sup> and tularemia.

Vesicular and vesiculopustular rashes that can resemble varicella are seen in rickettsial infections<sup>224,225</sup> including rickettsialpox.<sup>226</sup> Among 55 patients with African tick-bite fever with rash (46% of the total cases), lesions were maculopapular in 51%, vesicular in 45%, and purpuric in 4%.<sup>114</sup> A number of viral infections, some widespread (e.g., parvovirus, enteroviruses) and others focal (e.g., monkeypox, Ockelbo, Sinbis viruses), can cause vesicular rashes. In one study, of 29 travelers who had swum in freshwater pools in the Dogon area of Mali, West Africa, 28 became infected with schistosomiasis. Of those, 10 (36%) had cercarial dermatitis and 15 (54%) later developed Katayama fever.<sup>51</sup>

Erythema nodosum and other skin lesions may be present in acute coccidioidomycosis and histoplasmosis.<sup>185</sup> Urticarial skin lesions in the person with fever in addition to hypersensitivity reactions related to drugs should bring to mind early

hepatitis B and several helminthic infections (e.g., acute schistosomiasis or Katayama syndrome, fascioliasis, trichinosis, loiasis, and others). Fever is not a prominent finding in many helminthic infections, but of 20 patients with acute fascioliasis diagnosed at a university hospital in Spain, 12 (60%) had fever and 4 (20%) had urticaria. Although patients with fascioliasis can have undifferentiated fever, the presence of abdominal or right upper quadrant pain and eosinophilia are findings that can suggest this infection.<sup>227</sup> Vasculitic skin manifestations are associated with a variety of infections, collagen vascular diseases, and antimicrobial drugs.<sup>228</sup>

## Fever and Lymphadenopathy

The presence and location of any enlarged lymph nodes should be noted on initial and follow-up examinations. Localized lymphadenopathy frequently appears adjacent to the entry of a pathogen. Generalized lymphadenopathy more often suggests systemic infection though it does not necessarily indicate infection of lymphoid tissue. Prominent local enlargement of nodes in tularemia, leishmaniasis, plague, cat-scratch disease (*Bartonella*), syphilis, primary herpes simplex, lymphogranuloma venereum (LGV), and some rickettsial infections may suggest a nearby portal of entry through the skin or genital tract. Generalized lymphadenopathy is found in many viral infections (including infectious mononucleosis and acute HIV infection), rickettsial infections,<sup>229</sup> leptospirosis, brucellosis, and relapsing fever, among others. Of 22 patients with rickettsiosis imported to Germany, lymphadenopathy was found in 14 (64%); an eschar was noted in 55% of patients with *Rickettsia conorii* infection and in one patient with scrub typhus.<sup>230</sup>

Lymphadenopathy can be found in several protozoan infections—trypanosomiasis (both African and American), leishmaniasis, and toxoplasmosis—but not malaria. Acute lymphangitis, lymphadenitis, orchitis, and epididymitis are characteristic features of filariasis.<sup>47</sup> These episodes frequently are recurrent. Local lymphadenopathy can precede the development of skin lesions in *Leishmania braziliensis* infections.

## Persistent and Relapsing Fevers

Persisting and recurring fevers present a clinical challenge. Reviews since 1961 of persons in the United States with fevers of unknown origin (typically defined as fevers lasting 3 weeks or longer), excluding persons with HIV infection or other immunocompromising conditions, have found infections in 30% to 36%, neoplasms in 10% to 31%, collagen-vascular diseases in 9% to 16%, and miscellaneous causes in 18% to 25%.<sup>231–234</sup> In these series, 7% to 12% remained undiagnosed. An analysis of causes of fever of undetermined origin in 129 patients hospitalized in Cairo, Egypt, in 1971 to 1973 found that infections accounted for the majority (60%) of the fevers and neoplasms for only 14%. In that setting, the most commonly diagnosed infections were enteric fevers (salmonellosis), tuberculosis, pyelonephritis, sepsis, endocarditis, brucellosis, visceral leishmaniasis, and amebic hepatitis.<sup>235</sup> A 1990 Egyptian study of 133 patients with undiagnosed fever lasting at least 3 weeks again found infectious diseases in the majority (56%).<sup>236</sup>

Among 43 pediatric patients (age 1 to 14 years) in Egypt with fever lasting at least 3 weeks, 30 (69.7%) had parasitic infections.

Schistosomiasis (23.3%), visceral leishmaniasis (16.3%), toxoplasmosis (11.6%), and malaria (4.7%) were the most commonly diagnosed parasitic infections. In addition, more than 10% of patients had a parasitic infection in association with another infection or disease. The most commonly identified bacterial infections were typhoid fever (11.6%), tuberculosis (7.0%), and urinary tract infection (4.7%).<sup>237</sup>

Viral infections occupy a less important role in chronic than in acute fevers. Perhaps the most common viral cause of prolonged fever is CMV infection.<sup>238</sup> EBV and HIV can also cause prolonged fever, often associated with atypical lymphocytosis. Among 41 patients with acute illness associated with HIV seroconversion, the most common symptoms were fever, sore throat, fatigue, weight loss, and myalgia. The median duration of symptoms was 14 days though symptoms persisted 4 weeks or longer in 32%.<sup>129</sup> Physical findings in patients with acute HIV infection often include rash (70%) and lymphadenopathy (77%).<sup>239</sup> In the evaluation of a person with prolonged fever, it is important to determine the HIV status, since the range of infections and the probabilities of each will be altered if the person is HIV infected.

Causes of chronic or persistent fevers include protozoa, e.g., malaria, amebic liver abscess, trypanosomiasis (American and African), and visceral leishmaniasis; chronic bacterial infections such as brucellosis,<sup>240</sup> tuberculosis, bartonellosis, and melioidosis; fungal infections, such as histoplasmosis, coccidioidomycosis, and paracoccidioidomycosis;<sup>241</sup> and a few helminthic infections, such as visceral larva migrans, fascioliasis, and schistosomiasis.

Visceral leishmaniasis is an important cause of chronic fevers that can be acquired in some temperate as well as tropical areas of the world.<sup>242–244</sup> For example, of 89 patients with visceral leishmaniasis in France in 1986–1987, 70 (79%) had acquired the infection in France. Imported cases came primarily from other Mediterranean countries.<sup>242</sup> In recent years visceral leishmaniasis has emerged as an important opportunistic infection in persons with acquired immunodeficiency syndrome (AIDS) living in southern France, Spain, and Italy.

Melioidosis is an infection that can have an acute and fulminant, subacute, or chronic course and can reactivate years after the initial exposure. Manifestations are protean. Infection can involve lung, skin, and soft tissues and any part of the body via bacteremic spread. Pulmonary changes, including cavitation, can mimic tuberculosis.<sup>245,246</sup> In a series of 602 patients seen in one hospital in Thailand over a 5-year period, in-hospital mortality was 42%. Among 118 adult patients with long-term follow-up, 23% had culture-proven relapses, occurring 1 to 290 weeks after discharge (median, 21 weeks).<sup>247</sup> The adequacy of initial antimicrobial treatment influenced the probability of relapse. Recrudescence of infection has been reported as long as 26 years after initial infection.<sup>248</sup>

Ehrlichiosis is another potentially treatable cause of prolonged fever. In a series of 41 cases of human ehrlichiosis identified between 1989 and 1993, six patients manifested protracted fever as the principal finding.<sup>249</sup> The reported duration of fevers ranged from 17 to 51 days.

Chronic or recurrent fevers can be the result of uncommon complications of an infection, sometimes related to hematogenous seeding of tissues, for example, Q fever endocarditis, brucella osteomyelitis or endocarditis, and splenic or liver

abscesses secondary to melioidosis.<sup>250</sup> In a prospective study of 530 patients with brucellosis in Spain followed for at least a year after treatment, 86 patients relapsed (97 relapse episodes). The mean interval between completion of therapy to relapse was 69.1 days (range, 7 to 350 days). Among recognized relapses, 95% occurred within 6 months of the end of therapy.<sup>251</sup> Less effective initial therapy appeared to be an important risk factor for relapse.

Relapsing fevers are commonly seen with relapsing fever due to *Borrelia*<sup>252–256</sup> and with malaria. They can also occur

with cholangitis (which can be associated with parasites as well as with stones and other biliary disease), chronic meningococcemia,<sup>257</sup> rat-bite fever (*Streptobacillus moniliformis*), brucellosis, filariasis, infective endocarditis, visceral leishmaniasis, trypanosomiasis, Hodgkin's disease, Whipple's disease,<sup>196</sup> and many other diseases.<sup>258,259</sup> Pyomyositis can cause undifferentiated fever in its early stages. It is usually seen in persons who have lived in tropical areas.

The fever that accompanies acute schistosomiasis (Katayama fever) and fascioliasis<sup>227</sup> can persist for weeks. In an outbreak of schistosomiasis among travelers, 15 of 29 who were infected developed Katayama syndrome with typical symptoms being fever, drenching sweats, myalgia, and prostration. The median duration of symptoms was 12 days with a range of 4 to 46 days.<sup>51</sup> Visceral larva migrans<sup>260</sup> can cause prolonged or intermittent fevers. The associated findings of leukocytosis, eosinophilia, and enlarged liver suggest the diagnosis.

Box 124-6 lists some of the more common causes of persisting and intermittent or relapsing fevers. The timing of onset of symptoms relative to exposures can be important in choosing the infection for greatest attention.

### Box 124-6 Persistent and Relapsing Fevers\*

#### **Bacterial**

Bartonellosis  
Brucellosis

Schistosomiasis  
Toxocariasis  
Trichinellosis

### Fevers and Remote Residence in Tropical Areas

Some infections can become clinically manifest years or decades after a person has left the place of acquisition. Late manifestations also may result from chronic sequelae of an earlier infection, even if active infection no longer is present. Persons with long residence in tropical areas are more likely to have acquired infections with late sequelae (Box 124-7). Some infections may require repeated exposure to produce symptomatic infection. The mechanisms by which remotely acquired infections can cause disease are several. Latent infection may reactivate, causing fevers and focal or systemic symptoms. Examples include tuberculosis, histoplasmosis, melioidosis, and leishmaniasis. Low-grade, persistent infections may expand (recrudesce), causing symptoms leading to diagnosis (e.g., malaria, Brill-Zinsser disease). The balance between host and microbe may tip in favor of the microbe in persons whose immunity has been altered by disease, drugs, or age. *Strongyloides* larvae may disseminate widely outside their usual gastrointestinal habitat, for example, in persons with cell-mediated immunosuppression, particularly those taking corticosteroids or coinfecting with HTLV-1.

*Salmonella enterica* serotype typhi may be carried in the biliary tree and remain inapparent unless mechanical (e.g., biliary obstruction) or other factors alter the local milieu. Worms with long life spans may breach a tissue barrier or cause chronic inflammatory changes leading to acute symptoms. Migration of ascaris can provoke acute pancreatitis or cause biliary obstruction.

Remote infection may cause scarring, obstruction, or alteration in structure that may predispose to superimposed infections or affect function. Scarring associated with renal tuberculosis can increase the risk of urinary tract infection with *E. coli* and other uropathogens, even if tuberculosis is inactive or has been treated and cured. Scarring of the urinary tract secondary to *Schistosoma haematobium* can be associated with bacterial infections and an increased risk of bladder cancer. Late sequelae of schistosomiasis may include portal and

\*List includes infections that may cause fevers with duration exceeding 3 weeks. Infections unrelated to tropical exposures (e.g., endocarditis, cholangitis, Hodgkin's disease, others) also can be associated with chronic and relapsing fevers.

**Box 124-7** Sequelae of Infections Acquired More Than 10 Years Earlier: Mechanisms and Examples**Reactivation of Latent Infection or Recrudescence of Inapparent Infection**

Brill-Zinsser disease (*Rickettsia prowazekii*)  
 CNS Chagas' disease  
 Coccidioidomycosis  
 Histoplasmosis  
 Leishmaniasis  
 Malaria (*Plasmodium malariae*)  
 Melioidosis  
 Paracoccidioidomycosis  
 Strongyloidiasis  
 Toxoplasmosis  
 Tuberculosis

**Persistent Infection and Recurrent Symptoms or Progressive Disease**

**Malignancy\***

Bladder cancer (*Schistosoma haematobium*)  
 Epstein-Barr virus  
 Hepatitis B and hepatitis C viruses (hepatocellular carcinoma)  
 Human immunodeficiency virus  
 Human T-cell lymphotropic virus type-I  
 Liver flukes

**Allergic, Hypersensitivity Reactions**

Rupture of echinococcal cyst

\*Papillomaviruses are also associated with cancers, but fever is not a feature of these infections.

pulmonary hypertension and polyps and fistulas of the bowel. Echinococcal cysts can impinge on the biliary tree, causing acute obstructive symptoms, or erode into the biliary tree and cause symptoms of acute cholangitis. Rupture of an echinococcal cyst can cause acute allergic symptoms, even anaphylaxis. Seizures can occur in patients with cysticercosis, even if parasites are no longer viable. Late complications of Chagas' disease typically do not include fever unless progression of infection occurs (e.g., in persons with AIDS or immunocompromised transplant patients).<sup>261–263</sup>

Clinical findings of hepatocellular malignancy related to remotely acquired, persistent infection with hepatitis B or hepatitis C virus may include fever secondary to tissue necrosis and the effects of the tumor.

**Processes Other Than Infection Causing Fever After Travel**

Travel itself may predispose to problems that cause fever. Already noted is the possibility of fever related to drugs taken for prophylaxis, empirical therapy, or for documented infection. Dependent edema of the lower extremity following prolonged travel may predispose to acute streptococcal cellulitis. Pulmonary emboli after prolonged air flights (dubbed the economy class syndrome because of the immobility imposed by cramped quarters<sup>264</sup>) may be associated with fever.<sup>265</sup>

Noninfectious diseases also cause fevers and should be considered if studies do not document infection.<sup>259,266,267</sup> Biopsy may be necessary to confirm a diagnosis in processes such as inflammatory bowel disease, malignancies, and lymphadenopathy of Kikuchi.<sup>268,269</sup> Hyperthyroidism may present with fever and diarrhea.

**Special Patients (HIV-infected, Immunocompromised, Pregnant)**

Many infections are more common, are more severe, or have altered clinical expression in persons who are immunocompromised. Opportunistic infections, such as tuberculosis, visceral leishmaniasis,<sup>270</sup> American trypanosomiasis, and histoplasmosis and other fungal infections may reactivate and become clinically apparent long after the infection was acquired. The person may be unaware of the initial event. An evaluation of 50 HIV-infected patients in Spain with unexplained fever lasting at least 4 weeks found the most frequent diagnoses were tuberculosis (42%), visceral leishmaniasis (14%), and disseminated *Mycobacterium avium* complex (14%).<sup>271</sup> Both host factors and exposure influence the relative proportions of various infections in different areas. Disseminated infection with the fungus *Penicillium marneffei* is occasionally seen in travelers, typically persons immunocompromised by HIV infection or other disease.<sup>272</sup> In its endemic area in Thailand and Southeast Asia it is an important opportunistic pathogen.<sup>273</sup> Clinical findings can be nonspecific and include fever, cough, malaise, and hepatosplenomegaly. Skin lesions may be present.<sup>273</sup>

It is important to know during the evaluation whether a woman patient is pregnant. The cause of fever may threaten the pregnancy, diagnostic tests and therapies may be harmful to the fetus, some infections can be transmitted transplacentally, and others infection, such as malaria and hepatitis E, are more severe in pregnant than in nonpregnant women.

**EVALUATION OF THE PATIENT WITH FEVER**

Patients with fever and recent tropical exposures always deserve careful evaluation even though similar symptoms might be treated casually in a person without a history of travel. It is helpful to construct a differential diagnosis encompassing potential bacterial, viral, parasitic and fungal pathogens based on initial history, geographic exposures, and clinical findings. Patients with confusion, hypotension, hypoxemia, or hemorrhagic skin rash need immediate attention and care. A more leisurely pace may be appropriate in patients with subacute or chronic fevers. Any patient with a potential exposure to malaria who is febrile or gives a history of fevers or chills must

**Box 124-8** Approach to Patient with Fever and History of Tropical Exposure**Initial Evaluation of Acute Fever**

- Complete blood count with differential
- Liver enzymes and function tests
- Blood culture—bacterial, viral, fungal (rarely)
- Urinalysis (culture if abnormal)
- Blood smears for malaria
- Other tests
  - Serologic tests (save acute serum)
  - Urinary antigens (e.g., *Legionella* species)
  - Blood smears for *Babesia*, *Borrelia* causing relapsing fever
  - Bone marrow aspiration/biopsy: pathology and culture

**Tests to Consider for Focal Symptoms and Findings**

- Cough: chest film; sputum Gram's stain, acid-fast stain, stains for fungi; cultures for bacteria, mycobacterial species, fungi; wet preparation for ova (*Paragonimus* species) or larvae (hyperinfection with *Strongyloides stercoralis*); bronchoscopy
- Diarrhea: examination for fecal leukocytes (lactoferrin where available); blood (stool guaiac); toxin and culture for *Clostridium difficile*; ova and parasites, stool cultures; fecal antigens; endoscopy
- Sore throat: rapid streptococcal antigen test, culture, infectious mononucleosis absorption test (Monospot) (in appropriate clinical setting)
- Skin lesions: aspirate, scrapings, biopsy, Gram's stain, acid-fast stain, fungal stain, Wright-Giemsa stain (leishmania); culture for bacteria, fungi, mycobacteria, leishmania
- Lymphadenopathy: aspirate or biopsy, acid-fast stain, fungal stain, Wright-Giemsa stain (trypanosomes); culture
- Genital lesions or symptoms: pelvic examination, dark-field examination of ulcers, cultures for *Neisseria gonorrhoeae* and *Chlamydia trachomatis*, wet preparation for white blood cells, *Trichomonas vaginalis*, *Candida albicans*, and clue cells (bacterial vaginosis)
- CNS: CT scan, MRI, lumbar puncture with opening pressure and examination of CSF for cells, protein, glucose, bacterial antigens; cultures for bacteria, *Mycobacterium tuberculosis*, fungi, viruses; India ink for *Cryptococcus neoformans* and cryptococcal antigen; VDRL, PCR for specific antigens; rarely, brain biopsy
- Abdominal pain: liver enzymes, amylase, stool examination (see above), abdominal radiographic series, CT scan, MRI
- Arthritis: aspirate—examine fluid for cells, protein, crystals; stains and cultures for bacteria, fungi, *Mycobacterium* species.
- Cardiac findings: echocardiogram (transesophageal or transthoracic), blood cultures (at least three sets), serology for Q-fever and brucellosis

be evaluated for malaria.<sup>274–277</sup> In general, most infections with the potential for rapid progression and fulminant course (e.g., falciparum malaria, hemorrhagic fevers, meningococcemia, plague, rickettsial infections) become manifest within a month of exposure. In thinking about the causes of fever in a person with diverse geographic exposures, one should always think first about possible diagnoses had the person not traveled, and then expand the differential diagnosis to include infections that may be related to exposures during travel. Omitting the first step can lead to pursuit of obscure or exotic diseases when the patient has a common readily treatable infection, such as acute pyelonephritis or streptococcal pharyngitis.

Initial studies will generally include a complete blood count (CBC) with a differential leukocyte and platelet estimate, thick and thin malaria smears, blood cultures, urinalysis, and liver function tests. Serum should be saved early in the course in the event serologic studies are indicated. Chest radiographs should be obtained in patients with pulmonary symptoms or signs and in persons with persistent, unexplained fever. Legionnaires' disease, for example, can cause undifferentiated fever in the absence of cough. Serologic studies for HIV infection should be requested in persons with persistent fevers and those with possible exposures during travel. Studies that may yield useful information if initial studies are unrevealing include repeated malaria smears, blood cultures, serial CBCs, differentials, and liver function testing. Repeated physical examinations may yield new information with the development of new

skin findings, lymphadenopathy, or a tender liver or spleen. Although many of these findings may not give the diagnosis, they may help refine the list of considerations, allowing a more focused and efficient path to the diagnosis. Occasionally a patient will have two unrelated infections, both requiring specific interventions.<sup>278,279</sup> Box 124-8 outlines an approach to patients with fever and a history of tropical exposures.

**SOURCES OF ASSISTANCE**

Electronic communication networks bring resources to clinicians throughout the world and provide linkages to colleagues who can provide information unavailable in textbooks. Physicians who regularly care for persons who have lived or traveled in other parts of the world need access to several kinds of information: current data about the epidemiology of diseases in specific geographic regions, assistance with the diagnosis of rare diseases, assistance with public health support, sources of and information about rarely used drugs, and names of drugs and translations of drug names that patients may have received in other parts of the world. Some of this information can be obtained through regular communications from the CDC and World Health Organization (WHO) and through electronic networks such as ProMED<sup>26</sup> and those available to members of the American Society of Tropical Medicine and Hygiene and the International Society of Travel Medicine.

## EMERGING DISEASES AND DIFFICULTIES

Diseases are not fixed in distribution, clinical expression, or response to antimicrobials.<sup>24</sup> Hosts also change. As the hepatitis A and hepatitis B vaccines are now more widely used, these infections have become uncommon in travelers to developing countries. Conversely, increasing antimicrobial resistance of bacteria and protozoa may increasingly limit choices for prophylaxis, empirical therapy, and treatment. Persons who are older and those with chronic diseases are traveling more regularly and to more remote destinations. Multiple diverse geographic exposures are becoming a common part of the carefully taken medical history. New technologies, such as polymerase chain reaction (PCR), may reduce some of the frustrations currently encountered in making rapid specific diagnoses. Even with these advances in diagnosis and communication, evaluation and management of the patient with fever will continue to be a challenge, requiring a thoughtful and systematic approach and broad knowledge or access to it.

# Eosinophilia

MARY E. WILSON  
PETER F. WELLER

## INTRODUCTION

Eosinophilia develops as an immunologically mediated response in association with diverse processes, including allergic, neoplastic, and infectious diseases (Box 125-1). Eosinophilia is a hematologic marker that warrants attention and serves as a clue to help direct a diagnostic workup. Although many diseases are associated with eosinophilia, the presence of eosinophilia in a person with tropical exposures suggests the possibility of specific parasitic infections. Eosinophilia is notably common in association with multicellular, helminthic parasites, especially those in tissues.<sup>1</sup> Before embarking on an exhaustive search for parasitic infections in a patient with eosinophilia, however, it is prudent to consider common noninfectious causes of eosinophilia, such as allergic diseases and drug-induced hypersensitivity reactions.<sup>2</sup>

Eosinophilia in parasitic infections is the result of dynamic interactions that are influenced by host factors, the stage of parasite development, the location of the parasite within the human host, and the parasite burden, among other factors. Eosinophilia may wax and wane. Parasites often associated with eosinophilia may not provoke an identified eosinophilic response in all patients or at all times. Parasites may elicit a localized eosinophilic tissue response that is not reflected by an increase in peripheral blood eosinophil numbers. This chapter describes the immunobiology of the eosinophil, the causes of eosinophilia with special attention to parasitic infections, and the evaluation of the patient with eosinophilia.

## OVERVIEW

Most unicellular pathogens do not provoke an eosinophilic response.<sup>1,2</sup> In contrast, presentation of antigenic material from multicellular parasites, notably helminths, is a common and potent stimulus to eosinophilia (Box 125-2). Relative to most bacterial and viral pathogens, helminths are large and have a long life span, often measured in years or even decades.<sup>1</sup> Unlike viral and bacterial pathogens that multiply in human hosts, most helminths cannot undergo their complete reproductive cycles in humans; hence the numbers of adults are limited by the number of eggs or larval forms acquired by the human. Prolonged or repeated exposures may be required for a human to acquire sufficient parasites to cause symptomatic infection. Many helminthic infections cause few or no symptoms or only intermittent findings. For instance, of 303 persons who had serologic evidence of current or past schistosome infection after visiting or living in Malawi, 62% had no symptoms.<sup>3</sup>

In addition, because of the lengthy developmental period and longevity of helminthic parasites, symptoms may begin months or years after exposures in endemic regions. For example, in 6 of 20 Peace Corps workers who developed loiasis during a 2-year stay in Gabon, only one had demonstrable disease within the first year.<sup>4</sup> Thus, the time period between possibly relevant exposures and the onset of clinical or other evidence of infection is much longer than usually considered in obtaining a medical history for most clinical evaluations.

Most protozoan infections are not associated with eosinophilia. Exceptions are *Isospora belli*<sup>5</sup> and possibly *Dientamoeba fragilis*,<sup>6</sup> which have been reported to be associated

## Box 125-1 Eosinophil-associated Diseases and Disorders

### "Allergic" Diseases

Atopic and related diseases  
Medication-related eosinophilias

### Infectious Diseases

Parasitic infections, mostly with helminths  
Specific fungal infections  
Other infections—infrequent

### Hematologic and Neoplastic Disorders

Hypereosinophilic syndrome  
Leukemia, variants of the M-4 phenotype of acute myelomonocytic leukemia  
Lymphomas, especially nodular sclerosing Hodgkin's; some T- and B-cell lymphomas  
Tumor-associated: on occasion with large cell non-keratinizing cervical tumors, large cell undifferentiated lung carcinomas, squamous carcinomas (vagina, penis, skin, nasopharynx), adenocarcinomas (stomach, large bowel, uterine body), and transitional bladder cell carcinoma  
Mastocytosis

### Diseases with Specific Organ Involvement

Skin and subcutaneous diseases (e.g., blistering diseases, bullous pemphigoid, pemphigus vulgaris, dermatitis herpetiformis, herpes gestationis, and drug-induced lesions)  
Pulmonary diseases (e.g., acute or chronic eosinophilic pneumonia, allergic bronchopulmonary aspergillosis)  
Gastrointestinal diseases (e.g., eosinophilic gastroenteritis)  
Neurologic diseases (e.g., eosinophilic meningitis)  
Rheumatologic diseases (e.g., Churg-Strauss vasculitis)  
Cardiac diseases (e.g., endomyocardial fibrosis)  
Renal diseases (e.g., drug-induced interstitial nephritis, eosinophilic cystitis, dialysis)

### Immunologic Reactions

Specific immunodeficiency diseases (hyper-IgE syndrome, Omenn's syndrome)  
Transplant rejection

### Endocrine

Hypoadrenalism

### Other

Atheroembolic disease  
Irritation of serosal surfaces  
Inherited

Modified from Weller PF: Eosinophilia and eosinophil-related disorders. In Adkinson NF Jr, Yunginger JW, Busse WW, et al (eds): Allergy: Principles and Practice, 6th ed. St. Louis, Mosby-Year Book, 2003, p 1105.

**Box 125-2** Key Concepts: Eosinophils in Parasitic Infections

- Elevation is caused primarily by helminthic parasites that reside in tissues. Most protozoan parasitic infections are not associated with eosinophilia.
- Eosinophils may be prominent during only one stage of parasite development. Migration of parasites within tissues is often associated with high-grade eosinophilia. Chronic parasitic infections in antigenically sequestered sites (e.g., echinococcal cysts) or solely within the gut lumen (e.g., adult *Ascaris* or tapeworms) may not provoke an eosinophilic response. Release of antigenic material when parasites die or when walls protecting parasites are breached may lead to increased eosinophilia.
- Eosinophil levels may wax and wane; many factors unrelated to the helminthic infection influence the level of blood eosinophilia. Acute bacterial, viral, and protozoal (e.g., malaria) infections suppress eosinophilia.
- High-grade eosinophilia and symptoms may be prominent during the prepatent period and before the diagnosis can be confirmed by finding eggs or diagnostic forms of the parasite in tissues. Serologic tests may help in early diagnosis.
- The degree of eosinophilia and other clinical manifestations caused by helminthic infections may differ between long-term residents of endemic regions and short-term visitors, being more prominent in the latter.
- Many infections associated with eosinophilia cause no or intermittent symptoms; first symptoms may develop months or years after exposure. Many helminths are long-lived with life spans that can exceed a decade.
- Multiple infections may be present, especially in long-term residents of tropical areas. Finding intestinal eggs or certain parasites does not confirm that they are the cause of the eosinophilia. In a patient with *Ascaris* eggs and moderate or high-grade eosinophilia, the search for the cause of eosinophilia should continue.
- Absence of eosinophilia does not exclude a parasitic infection typically associated with eosinophilia.

with increases in eosinophils. In some reports of these infections, other causes of eosinophilia had not been excluded. Eosinophilia and acute symptomatic eosinophilic myositis has been found in association with the coccidian parasite *Sarcocystis*.<sup>7,8</sup> In Malaysia, the parasite was found in 21% of routine autopsies when tongues were carefully examined.<sup>9</sup> More studies are needed to define whether or how often *Sarcocystis* causes eosinophilia. In general, however, the finding of eosinophilia in a patient with a protozoan infection should prompt a search for another, principally helminthic, infection or an alternative noninfectious process to explain the eosinophilia.

Only a few bacterial, viral, and fungal infections are associated with eosinophilia (Box 125-3). As noted in the following sections, acute bacterial or viral infections characteristically produce eosinopenia.<sup>10</sup> Likewise, acute protozoan infections, including malaria,<sup>11,12</sup> will suppress eosinophilia, including that caused by helminthic infections, during the intercurrent infection. It is likely that bacterial superinfections that complicate hyperinfection strongyloidiasis contribute to suppression of eosinophilia that might otherwise be an obvious clue to the presence of strongyloidiasis. When eosinophilia is observed in bacterial infections, it is in the resolving phase, as occurs with

Myiasis

scarlet fever, or is attributable to a hypersensitivity reaction to a drug used for treatment. Two fungal diseases are associated with eosinophilia: aspergillosis, in the form of allergic bronchopulmonary aspergillosis,<sup>13</sup> and coccidioidomycosis.<sup>14</sup> Blood eosinophilia, peaking during the second or third week of illness, occurs with primary coccidioidomycosis.<sup>15</sup> Eosinophilia, at times prominent, also may develop with disseminated coccidioidomycosis.<sup>16,17</sup> A few reports note eosinophilia in patients with infestations caused by myiasis<sup>18</sup> and scabies.<sup>19</sup>

**PATHOGENESIS**

Eosinophils are bone marrow–derived leukocytes. Eosinophilia develops when specific cytokines, granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin (IL)-3, and IL-5 stimulate enhanced eosinophilopoiesis. Of these three eosinophil growth factor cytokines, IL-5 is principally responsible for increases in eosinophilopoiesis and eosinophilia in helminthic, allergic, and other diseases.<sup>20</sup> In humans, enhanced eosinophilopoiesis within the marrow requires over a week to increase blood eosinophilia. IL-5 also acts more rapidly to increase blood eosinophilia by mobilizing a marginated pool of preformed eosinophils resident within the marrow. IL-5 is a cytokine produced by Th2-like CD4+ T lymphocytes (as well as other cells, including eosinophils); and eosinophilia is frequent with immune responses characterized by Th2-like T-cell activation, including those elicited by helminthic parasite infections and associated with allergic diseases.<sup>21</sup> In both of these, enhanced IgE production is usually present.<sup>21</sup> In other diverse diseases associated with eosinophilia (see Box 125-1), the mechanisms leading to eosinophilia are not yet delineated. GM-CSF, IL-3, and IL-5 also act on mature eosinophils to prolong their survival by antagonizing apoptosis and to enhance their effector functions.

Although Th2-like T-cell responses lead to eosinophilia, it remains uncertain how specific parasitic or allergic diseases characteristically stimulate Th2-type responses. Some findings, such as the capacity of Sephadex beads embolized into the lungs to

elicit eosinophilia, suggest that eosinophilia may develop not in response to specific antigens, such as those of helminths, but rather from the immune response to large particulate objects. Nevertheless, it remains possible, but not yet defined, that specific features of helminthic antigens, as well as their particulate presentation, influence the initial antigen presentation process that leads to Th2-like lymphocyte responses and consequent eosinophilia. As noted in the following discussion, eosinophilia is most prominent with helminthic infections when parasites are migrating through or beginning to localize within tissues.

## IMMUNOBIOLOGY

Eosinophils are primarily tissue-dwelling leukocytes normally distributed within specific tissues. Eosinophils are several hundred-fold more abundant in tissues than in blood, and eosinophil numbers are greatest in those tissues with a mucosal epithelial interface with the environment, including the respiratory, gastrointestinal, and lower genitourinary tracts. The life span of eosinophils is longer than that of neutrophils. Eosinophils probably survive for weeks within tissues.

In patients with eosinophilia of parasitic and other causes, blood eosinophils often exhibit morphologic and functional alterations consequent to being “activated” in vivo. These changes include increased metabolic activity, diminished density (“hypodense”), enhanced antibody-mediated cytotoxicity, and enhanced leukotriene  $C_4$  formation. Morphologic changes include cytoplasmic vacuolization, alterations in granule numbers and size, and increased lipid body formation, all visible by light microscopy, and losses within specific granules of the matrix or eosinophil major basic protein (MBP)-containing cores, visible only by electron microscopy.<sup>22</sup> This phenotypic alteration can be reproduced in vitro by exposure of eosinophils to the eosinophil growth factor cytokines, GM-CSF, IL-3, and IL-5. While these eosinophil growth factor cytokines contribute to eosinophil “activation,” these cytokines alone do not elicit all measures of eosinophil activation. Other cytokines or tissue- or extracellular matrix-derived activating stimuli are likely to be involved in augmenting the functional capabilities of eosinophils.

The immunologic functions of eosinophils remain the subject of intense investigation. In addition to functioning as endstage effector leukocytes, eosinophils likely have additional roles in interacting with lymphocytes and other cells. As effector cells, eosinophils are capable of releasing specific lipid mediators, such as leukotriene  $C_4$ , and are a source of a range of granule-stored cytokines. In addition, eosinophils uniquely contain specific, highly positively charged (“cationic”) proteins within their cytoplasmic granules. These eosinophil granule cationic proteins include MBP and eosinophil cationic protein (ECP). The release of these granule proteins can damage host tissues. A beneficial effect of these granule proteins is that they can contribute to the killing of helminthic parasites. The extent to which eosinophils are involved in the immune responses to helminthic parasites, and especially their early larval forms, to help kill these parasites in vivo is still not certain.<sup>21,23</sup>

In patients with marked eosinophilia, eosinophils may cause organ damage, most notably to the heart. The damage to the heart, ranging from early necrosis to subsequent endomyocardial thrombosis and fibrosis, is the same with varied eosinophilic conditions. Thus, endomyocardial thrombosis and fibrosis develop with eosinophilia associated with the hypereosinophilic syndromes,<sup>24</sup> carcinomas and lymphomas,

and parasitic infections, including trichinellosis, visceral larva migrans, loiasis, or other filarial infections.<sup>25–29</sup> Pathologically, eosinophilic endomyocardial fibrosis, originally described by Löffler,<sup>30</sup> is identical to tropical endomyocardial fibrosis.<sup>31,32</sup> While diverse eosinophilic diseases can cause identical forms of cardiac disease, many patients with sustained eosinophilia never develop cardiac disease. Thus, the pathogenesis of eosinophil-mediated cardiac damage involves both the presence of increased eosinophils and other, as yet ill-defined, stimuli for recruitment or activation of these leukocytes.

## HOST FACTORS THAT INFLUENCE EOSINOPHIL RESPONSES

Several evaluations of the upper limits of normal blood eosinophil numbers have been published, and based on these, blood eosinophilia is clearly present when eosinophils are in excess of 450 cells per microliter of blood. Published studies use cutoffs that range from 350 to 500 cells per microliter of blood. Increased percentages, but not absolute numbers, of blood eosinophils (pseudoeosinophilia) due to leukopenia in another white blood cell line can be misleading.

Many host factors and other stimuli influence peripheral blood eosinophil levels (Box 125-4). Blood eosinophil numbers vary diurnally, with levels being highest in the early morning and lowest at about noon. Levels are higher in the neonatal period and decline with age. Eosinophil levels fall during pregnancy; during the stress of delivery they almost disappear from the peripheral circulation.<sup>33</sup> Epinephrine causes a sharp fall in circulating eosinophils, after a transient increase. The  $\beta$ -adrenergic blocker propranolol increases counts by about 30% and can block the effect of epinephrine.<sup>34</sup> Injection of 100 mg hydrocortisone is followed by a decrease in peripheral eosinophils to 35% of control levels within 1 hour, and blood eosinophils are nearly absent 4 hours after the steroid administration.<sup>34,35</sup> Corticosteroids inhibit tissue accumulation of eosinophils, probably by several mechanisms, including promoting eosinophil apoptosis (“programmed cell death”).<sup>36</sup> Acute pyogenic infections, including bacterial and viral infections, as noted previously, and other processes causing acute inflammation are associated with a decline in blood eosinophils.<sup>34,35,37</sup> This can transiently erase a peripheral blood eosinophilia. Eosinophils drop during acute malaria, even if previously elevated.<sup>11,12</sup> Depression of eosinophils in malaria persisted beyond the clearance of fever and parasitemia, and was followed by an increase in eosinophils in convalescence.<sup>12</sup> When it is important to know whether a patient has eosinophilia, a blood differential count should be repeated after a patient has recovered from an acute intercurrent infection.

### Box 125-4 Factors That Lower Eosinophil Counts

- Acute bacterial and viral infections; acute malaria
- Corticosteroids—endogenous and exogenous
- Acute stress
- Pregnancy (counts especially low during stress of delivery)
- Immunosuppressive states (also less elevation of IgE; sensitivity of serologic tests may be lower)
- Epinephrine (sharp fall after initial transient rise; can be inhibited by  $\beta$ -blockers)

## PATTERNS

Characteristics of the eosinophil response that may be useful in assessing more likely causes of eosinophilia include level, duration, pattern (constant vs. intermittent), and associated symptoms. If a person has had tropical exposures, the timing of onset of eosinophilia in relation to those exposures may help in the evaluation. Eosinophilia should be characterized by level, not simply as present or absent. Absolute eosinophil counts of

greater than 3000 per microliter are categorized as marked or high grade eosinophilia. Several different patterns of eosinophilia may be seen in relation to parasitic infections. Factors that influence these patterns include the type of parasite, the stage of parasite development, the location within the human host, the integrity of barriers between parasite and host, and the viability of the parasite, as well as many attributes of the host (Table 125-1).<sup>1</sup> In some parasitic infections, eosinophilia is

**Table 125-1 Helminthic Infections and Eosinophilia**

Parasitic Infection	Main Body Site	Diagnosis
<i>Angiostrongylus cantonensis</i>	CNS	Larvae in CSF
<i>Angiostrongylus costaricensis</i>	GI	Tissue biopsy (ileum, colon)
Anisakiasis	GI	Parasite via endoscopy or biopsy
Ascariasis	GI, lung (larvae)	Stool examination; sputum examination or BAL for early infection (larvae)
<i>Capillaria hepatica</i>	Hepatobiliary	Biopsy of liver
<i>Capillaria philippinensis</i>	GI	Eggs, larvae, adults: stool, duodenal or jejunal aspirate, biopsy
Clonorchiasis	Hepatobiliary	Stool examination, duodenal aspirate; serology
Coenurosis	Many, including CNS	Parasite in tissue
Cysticercosis	Many, including CNS, soft tissues	Tissue examination, serology
Dicrocoeliasis	GI	Eggs in stool, duodenal aspirate, bile
Dirofilariasis	Lung, subcutaneous	Morphology in biopsied tissue
Dracunculiasis	Soft tissues, skin	Morphology of worm
Echinococcosis	Liver, lung, CNS, other	Morphology in tissue or aspirate; serology
Echinostomiasis	GI	Eggs in stool
Enterobiasis	GI, perianal	Eggs or worms in perianal area
Fascioliasis	Hepatobiliary	Eggs in stool, duodenal aspirate
Fasciolopsiasis	GI	Eggs in stool
Filariasis		
Lymphatic: <i>Wuchereria</i> , <i>Brugia</i>	Blood, lymphatics	Microfilariae in blood; worm in tissue
Loiasis	Subcutaneous, eye	Removed worm; microfilariae in blood
Mansonellae		
<i>M. ozzardi</i>	Blood, skin, body cavities	Microfilariae: blood, skin biopsy
<i>M. perstans</i>	Blood, body cavities	Microfilariae: blood, fluids; adult in tissue
<i>M. streptocerca</i>	Skin, subcutaneous tissues	Microfilariae: skin biopsy, snips; adult in tissue
Onchocerciasis	Skin, subcutaneous tissues, eye	Microfilariae: skin snips, blood, eyes; adults: tissue
Tropical pulmonary eosinophilia	Lung	Serology
Gnathostomiasis	Subcutaneous, other tissues	Morphology in surgical specimen
Heterophyiasis	GI	Eggs in stool
Hookworm	Skin (transient), GI, lung (larvae)	Eggs in stool
Hymenolepiasis	GI	Eggs in stool
Metagonimiasis	GI	Eggs in stool
Opisthorchiasis	Hepatobiliary	Eggs in stool, duodenal aspirate, bile
Paragonimiasis	Lung, CNS, subcutaneous	Eggs: sputum, BAL, feces, pleural fluid
Schistosomiasis		
Schistosomal dermatitis	Skin	Morphology on biopsy
<i>S. haematobium</i>	Urinary tract, rarely CNS	Eggs in urine, tissue biopsy; serology
<i>S. intercalatum</i>	Liver, GI (venules of bowel), rarely CNS	Eggs in stool, biopsy
<i>S. japonicum</i>	Liver, GI (venules of bowel), rarely CNS	Eggs in stool, biopsy; serology
<i>S. mansoni</i>	Liver, GI (venules of bowel), rarely CNS	Eggs in stool, biopsy; serology
Sparganosis	Subcutaneous, multiple sites	Parasite in surgical specimen
Strongyloidiasis	GI, lung (larvae), skin (episodic)	Larvae in stool, duodenal aspirate; serology
Trichinellosis	GI (early), muscle, CNS	Muscle biopsy; serology
Trichostrongyliasis	GI	Eggs in stool or duodenal aspirate
Trichuriasis	GI	Eggs in stool, worms on proctoscopy
Visceral larva migrans		
<i>Toxocara canis</i> , <i>Toxocara cati</i>	Liver, eye, lung (larvae)	Larvae in tissue; serology
<i>Baylisascaris procyonis</i>	CNS, eye, other	Identification of larva

BAL, bronchoalveolar lavage; CNS, central nervous system; CSF, cerebrospinal fluid; GI, gastrointestinal.

**Table 125-2** Common Parasitic Causes of Marked Eosinophilia

Parasite/Disease	Magnitude	Comment
Angiostrongyliasis	High early	
Ascariasis	Moderate to high (larval migration)	Often absent with adult worms
Clonorchiasis	High early	May wax and wane in chronic infection
Fascioliasis	High early	May wax and wane in chronic infection
Fasciolopsiasis	High early	
Filarial infections		
Loiasis	High	Especially in expatriates
Mansonellosis	Can be high	
Onchocerciasis	Can be high	Normal eosinophil counts in up to 30%
Tropical pulmonary eosinophilia	High	
Gnathostomiasis	May be high	Wax and wane in chronic infection
Hookworm	High during larval migration	Persistent low to moderate
Opisthorchiasis	High early	
Paragonimiasis	High in early infection	Low or absent late
Schistosomiasis	High during early infection	Low or absent in chronic infection
Strongyloidiasis	High during larval migration	Low to moderate in chronic infection
Trichinellosis	High during acute infection	Absent late
Visceral larva migrans	High to moderate	May persist months or longer

prominent only during one stage of parasite development. An example is the common intestinal parasite *Ascaris lumbricoides*, which provokes eosinophilia principally during the stage of larval migration through the lungs (see Chapter 109). Adult worms residing in the lumen of the gut typically do not cause an eosinophilic response. Some parasites, such as the tapeworms *Diphyllobothrium latum* and *Taenia saginata*, whose entire life in the human host takes place in the lumen of the gut, cause little or no eosinophilic response even though they can grow to impressive lengths and survive for decades. Table 125-1 lists the many helminthic infections associated with eosinophilia and the main body site affected by each.

Several parasites may induce high-grade eosinophilia during one stage of development (Table 125-2) followed by chronic low-to-moderate levels of eosinophilia. Acute schistosomiasis (Katayama syndrome)<sup>38,39</sup> (see Chapter 116) and the larval migration stage of *Ascaris*<sup>40</sup> and hookworms<sup>41</sup> may provoke high-grade eosinophilia, which declines during the chronic stages of infection. In experimental hookworm infections, blood eosinophilia increases progressively after 2 to 3 weeks of infection and peaks between 5 and 9 weeks before gradually diminishing. In recipients of 45 to 50 infective larvae, peak eosinophil counts ranged from 1350 to 3828 cells per microliter in one study.<sup>41</sup> In untreated hookworm infections, eosinophilia slowly diminishes but can persist for several years after experimental infection.<sup>42</sup> Persistence of eosinophilia has been attributed to the attachment of adult worms to the intestinal mucosa, causing mild tissue damage and a continuing stimulus to eosinophilia, especially in heavy infections.<sup>43</sup> The blood and pulmonary eosinophilia, so often characterized as “transient,” associated with the pulmonary migration phase of intestinal parasites (*Ascaris*, hookworms) typically persists for weeks or months.<sup>40,44,45</sup> The eosinophilia with strongyloidiasis (see Chapter 111) often fluctuates over time, being high during pulmonary migration and low to moderate during chronic infection. During hyperinfection syndromes, eosinophilia can be prominent or absent, influenced by host characteristics

and suppression due to corticosteroids or concomitant bacterial infection.<sup>46</sup> The dramatic eosinophilia seen with acute trichinellosis usually disappears when a fibrous capsule forms around the larvae in muscles (except with the nonencapsulating species *Trichinella pseudospiralis*, which may cause a prolonged eosinophilic myositis<sup>47</sup>) (see Chapter 104). Parasites encysted in tissues, such as echinococcal cysts and cysticercosis, and physically isolated from the host by cyst walls, typically cause no eosinophilia unless disruption of the barrier allows leakage of antigen-rich material. Intermittent leakage of fluids from echinococcal cysts can transiently stimulate increases in blood eosinophilia and elicit allergic (urticaria, bronchospasm) or anaphylactic reactions.<sup>48,49</sup> Breaching of these barriers or disintegration with death of the parasite can lead to intense tissue reactions, increased eosinophilia, and acute symptoms in the host.

Adult parasites that live and migrate in tissues, such as *Loa loa* and *Gnathostoma spinigerum*, provide an ongoing stimulus to eosinophils.<sup>28,50</sup> Many filarial infections cause persistent eosinophilia (see Chapters 98 through 100).

The magnitude of eosinophilic responses and the presence and intensity of other symptoms may vary greatly depending on age at first exposures, the immunologic state of the host, and the number and timing of subsequent exposures. Temporary residents and long-term residents of endemic regions have different patterns of response to a number of helminths.<sup>51</sup> Loiasis in temporary residents of endemic regions is characterized by immunologic hyperresponsiveness, high-grade eosinophilia, and severe symptoms not seen in long-term residents of the same area.<sup>28</sup> Short-term residents are more likely to have Calabar swellings (95% vs. 16% for residents) and less likely to have detectable microfilaremia (10% vs. 90%) than the native population.<sup>28,52</sup> With schistosome infections, previously unexposed and nonimmune persons, and not long-term residents of endemic areas, may experience the Katayama fever syndrome in acute schistosomal infection.<sup>38,39,53</sup>

## EPIDEMIOLOGY

Published studies give some clues as to the more common infections associated with eosinophilia in persons who have visited or resided in tropical regions.<sup>54</sup> In a study from London (Hospital for Tropical Disease), 261 patients with eosinophilia (defined as  $>0.5 \times 10^9$  mL) from October 1997 to March 2002 were evaluated according to a standard protocol and with all diagnostic studies done at one laboratory.<sup>55</sup> A diagnosis related to tropical exposures was made in 64%, with the most common diagnoses being schistosomiasis (33%), strongyloidiasis (25%), hookworm (5.3%), onchocerciasis (4.2%), loiasis (2.3%), ascariasis (2.3%), and trichuriasis (2.3%). More than one parasitic infection was found in 17%. The predominant diagnoses varied by geographic areas of exposure. Schulte and colleagues in Germany found blood eosinophilia (defined as  $\geq 8\%$  of total WBC count) in 4.8% of 14,298 patients who were evaluated after return from developing countries.<sup>56</sup> The majority (73.6%) were born in Europe, and the median duration of travel was 35 days. One-third of those studied were asymptomatic. A definite diagnosis was made in 36%. In 18.9%, a specific helminth infection was found, with the most common helminth infections being schistosomiasis, hookworm, cutaneous larva migrans, strongyloidiasis, filariasis, and ascariasis. Travelers to Africa were more likely to have eosinophilia than those who visited the Indian subcontinent and Latin America. In returned travelers with higher levels of eosinophils ( $>16\%$ ), a helminth infection was found in 46.6%. In Belgium, of more than 8000 consultations for tropical diseases in 1991, 378 patients were found to have eosinophil levels greater than  $450/\mu\text{L}$ . Specific diagnoses were made in 170 patients, and parasites were detected 107 times, most commonly intestinal helminths and filarial and schistosomal species. When serologic tests and the Mazzotti test (see Chapter 100) were added as diagnostic criteria, intestinal helminthic infections were diagnosed in 19%, filarial infections in 13%, and schistosomal infections in 10% of patients.<sup>57</sup> In Indochinese refugees with persistent eosinophilia whose initial comprehensive screening failed to reveal a cause for the eosinophilia, the most commonly implicated infections after further investigation were hookworm (55%) and *Strongyloides* (38%) infections.<sup>58</sup> In this study, all patients with greater than 1000 eosinophils per microliter and 88% of those with greater than 500 eosinophils per microliter had documented infection with at least one helminth species. Of 40 patients assessed serologically by enzyme-linked immunosorbent assay (ELISA) for *Strongyloides* infection, 34 had a positive titer. Of the 34, *Strongyloides* larvae were found on a single stool examination in only 24 (71%).<sup>58</sup>

The prevalence of various helminthic causes of eosinophilia will vary from one population to another depending on their geographic origins, their long-term residence or shorter-term exposures in previously unexposed visitors, and their exposure-related activities. Although eosinophilia is a useful marker that suggests the possible presence of certain parasitic infections, many patients with these infections do not have eosinophilia when evaluated.<sup>59</sup> The absence of eosinophilia does not exclude the possibility of schistosomiasis, strongyloidiasis, and other infections commonly associated with eosinophilia. In a study of 1107 travelers with schistosomiasis seen in the UK, eosinophilia was present in only 44%.<sup>60</sup>

In the study by Schulte and colleagues, 45% of 92 returned travelers with schistosomiasis had eosinophilia.<sup>56</sup> When persons are known to have had intense exposure to parasites, such as schistosomes, screening tests for these infections are warranted in the absence of eosinophilia or specific symptoms.<sup>59</sup> Many helminthic infections persist for years or even decades in the human host (Box 125-5).

In contrast to persons who have not left temperate areas, persons with tropical exposures are more likely to have an infection as the cause of eosinophilia. Although infections associated with eosinophilia, such as visceral larva migrans, trichinellosis, or even strongyloidiasis, can be acquired in temperate regions, these infections account for a small percentage of cases of eosinophilia in nontravelers. Eosinophilia in most temperate regions is more likely to be caused by a process other than infection. As a rule of thumb, one should think first of parasitic infections in persons with eosinophilia and extensive tropical exposures and look first for nonparasitic infections in persons who have always lived in temperate climates.

Many infections associated with eosinophilia are seen primarily in persons with repeated or prolonged exposures. In general, cysticercosis, onchocerciasis, loiasis, lymphatic filariasis, paragonimiasis, and clonorchiasis are rare in persons with brief exposures (e.g., a few weeks or less). Although most persons with loiasis have had exposures in endemic regions lasting months or years, occasional infections have been documented in persons with less than one month of exposure.<sup>61</sup> In evaluating patients, it is useful to consider the prerequisites of symptomatic infection. Repeated exposures to a parasite may be required for the establishment of sufficient burden to cause symptomatic infections, for example, hookworm infections. Where a single exposure can lead to infection, the probability of infection in a visitor depends on how widespread and

accessible the areas of risk are. Development of acute schistosomiasis after a single brief exposure to infested water has been described repeatedly.<sup>38,53</sup> Because of differences in the immunologic response to parasites, as noted previously, a nonimmune visitor to an endemic region may develop severe symptoms and more marked eosinophilia with a small parasite burden relative to that in residents of the region.

## COMMON CAUSES

### *Strongyloides*

Among the helminths, the principal parasite that needs to be considered is *Strongyloides* since it frequently elicits eosinophilia of varying magnitudes; is often difficult to detect on stool examination; can persist for decades, even without causing major symptoms; and, importantly, can cause a disseminated, often fatal, disease (hyperinfection syndrome) in patients unsuspectingly given immunosuppressive corticosteroids (see Chapter 111).<sup>46</sup> In a study from Toronto General Hospital, of 51 consecutive individuals with *Strongyloides stercoralis* larvae documented in fecal specimens (and no other parasites found), 83% had eosinophilia (absolute eosinophil count >400 cells/ $\mu$ L) with a mean eosinophil count of 890 cells/ $\mu$ L.<sup>62</sup> Infection was longstanding in many; 22% had immigrated to Canada more than 10 years before diagnosis. Among 76 patients with strongyloidiasis 25% were asymptomatic, 42% had gastrointestinal symptoms, and 22% had skin complaints (primarily urticaria or pruritus).<sup>62</sup> In a study from the United Kingdom, eosinophilia was found in 88% (36/41) of travelers and 76% (44/58) of immigrants with larvae on fecal examination.<sup>63</sup> While low-level or varying eosinophilia may be the only clue to strongyloidiasis, at times the magnitude of hyper-eosinophilia suggests a hypereosinophilic syndrome.<sup>64</sup>

The capacity of *Strongyloides* larvae to mature within the host into filariform larvae which invade the mucosa of the colon or penetrate the skin (usually in the perianal region) means that ongoing reinfection enables the parasite to persist for the lifetime of the host. Illustrative of this potential chronicity of clinically unrecognized strongyloidiasis was the experience with US, UK, and Australian former World War II prisoners in Asia. For instance, in American ex-prisoners of war, who acquired strongyloidiasis while working on the Burma-Thailand railroad in the 1940s, 37% had evidence of previously unrecognized, but persisting, *Strongyloides* infections.<sup>65</sup> In this group, more than 90% were symptomatic with intermittent creeping eruption (larva currens), gastrointestinal symptoms, or urticaria,<sup>65</sup> but in other patients with persisting strongyloidiasis, eosinophilia may be the sole sentinel finding.<sup>66</sup>

The importance of deliberately considering *Strongyloides* infections, especially in those with eosinophilia, is based on the additional capacity of this infection to develop into disseminated, potentially fatal, disease (hyperinfection syndrome) if patients subsequently receive corticosteroids or become immunocompromised.<sup>46</sup> Thus, clinicians should carefully assess the probability of past exposure to *Strongyloides* in persons who will be given steroids or other immunosuppressive agents or who develop diseases associated with immunosuppression.<sup>46</sup> Rarely, disseminated strongyloidiasis has been reported in apparently immunocompetent persons.<sup>67</sup> Persons infected with

human T-cell lymphotropic virus type I (HTLV-I) are significantly more likely to be infected with *Strongyloides* than those who are uninfected with HTLV-I. Although certain groups of immunocompromised patients (especially those with hematologic malignancies, or on steroids, or with severe malnutrition) appear to be at increased risk for the *Strongyloides* hyperinfection syndrome, this has not been a frequently reported complication in human immunodeficiency virus serotype 1 (HIV-1)-infected persons in areas such as Brazil and sub-Saharan Africa, where both HIV-1 and *Strongyloides* infections are common. As discussed in the following sections, fecal examinations are insensitive, and ELISA serology is useful in detecting strongyloidiasis even when fecal examinations are unrevealing.<sup>58</sup>

### Schistosomes

Eosinophilia frequently accompanies schistosomiasis (see Chapter 116). Travelers from endemic areas may present with acute schistosomiasis, with less acute symptoms, or even without symptoms.<sup>68</sup> Many reports document sporadic cases and clusters of nonimmune persons with acute schistosomiasis after brief exposures in endemic regions.<sup>39,53</sup> Typical findings are spiking fevers, sweating, diarrhea, and dry cough that can persist for a month or longer. Pulmonary symptoms were noted in 8 of 60 nonimmune travelers seen in Israel with acute schistosomiasis, occurring 3 to 6 weeks after exposure.<sup>69</sup> Chest radiographs showed multiple small nodules and diffuse interstitial infiltrate.<sup>69</sup> Among 31 patients with acute schistosomiasis *mansoni* in Brazil, 90% had fever, 94% had diffuse abdominal pain, and liver enzymes were elevated in 38%.<sup>70</sup> Cough was reported by 81% and dyspnea by 52%.<sup>70</sup> All had eosinophilia.<sup>70</sup> In one study of 15 patients with Katayama syndrome, the median duration of illness was 12 days (range, 4 to 46 days).<sup>39</sup> Ten of 12 patients in this series had eosinophilia during the first 10 weeks of infection.<sup>39</sup> Other symptomatic presentations of schistosomiasis in travelers can include hematuria, hematospermia, or, uncommonly, transverse myelitis.<sup>71–73</sup> Infections can occur after a brief stay,<sup>74</sup> but for many schistosomiasis develops only after longer-term exposures in endemic regions. A British study of 173 expatriates with schistosomiasis acquired primarily in Africa found that the mean duration of stay in an endemic area was 7 years (range, 3 to 41 years) for those who were infected vs. 3 years for an uninfected control population returning from similar endemic regions.<sup>75</sup> A study of expatriates and visitors to Malawi found that serologic evidence of current or past schistosome infection increased directly with the length of stay in Malawi.<sup>3</sup> Seroprevalence was 48% in people resident 4 years or longer in contrast to 11% for those resident 1 year or less. Recreational freshwater exposure in Lake Malawi was an important source of infection.<sup>3</sup>

### Filariae

Eosinophilia is common in infections caused by the various filarial parasites (see Chapters 98 through 100), which differ by geographic region and are transmitted by biting insects (e.g., mosquito, black fly, or midge). In general, these infections are transmitted inefficiently and only rarely acquired after brief

stays in tropical regions. For lymphatic filariasis, early manifestations may include filarial fevers with lymphangitis.<sup>76,77</sup> With loiasis, reactions to adult worms are more common, especially in nonimmune short-term residents.<sup>28,52</sup>

### Human Immunodeficiency Virus Type 1

Occasional reports have noted increased levels of eosinophils in HIV-1-infected persons.<sup>78</sup> In a study of 855 HIV-infected persons in New York examined over 4 years, however, no single, consistent cause of eosinophilia could be identified.<sup>78</sup> Increased eosinophil levels appeared to result from a relative preservation of the eosinophil cell line (while other cell lines declined as the CD4 count decreased) in some patients and in others from the presence of truly increased eosinophils.<sup>78</sup> Increased eosinophil levels in HIV-infected subjects were more commonly associated with rashes, including eosinophilic folliculitis,<sup>79</sup> atopic dermatitis, and prurigo nodularis, in another study that suggested no extensive evaluation for eosinophilia was warranted.<sup>80</sup> Although some HIV-infected patients with eosinophilia have a definable cause, such as adverse drug reactions or adrenal insufficiency due to cytomegalovirus and other infections, in most instances no obvious cause can be identified, indicating that HIV infection may be associated at times with increased levels of eosinophils. While case reports have documented the occurrence of various eosinophilic syndromes in those infected with HIV,<sup>81–83</sup> these hypereosinophilic disorders are uncommon and likely not related to underlying HIV infection. A recent report has correlated the presence of eosinophilia, likely due to schistosomiasis, with the progression to active tuberculosis in HIV-1-infected Ugandans,<sup>84</sup> but the implications of this finding remain to be ascertained.

## COMMON SYNDROMES

### Pulmonary

Eosinophilic lung diseases are a heterogeneous group of disorders characterized by a common presence of increased eosinophils in inflammatory infiltrates in the airways or parenchyma of the lungs. The clinical presentation of pulmonary eosinophilia usually consists of symptoms referable to the respiratory system accompanied by an abnormal chest radiograph and blood or sputum (or bronchoalveolar lavage) eosinophilia. While the pathogenic mechanisms underlying many of the disorders are undefined, we have classified the pulmonary eosinophilias based on recognized etiologic agents and distinct clinical and pathologic patterns<sup>2</sup> (Box 125-6). Several helminthic infections can cause eosinophilic lung diseases, and these can be categorized based on the behavior of the parasites.

### Transpulmonary Passage of Helminth Larvae

This category, the true Löffler's syndrome, arises from reactions elicited by developing larvae that pass through the lungs as part of the parasite's initial developmental cycle in the human. For three helminthic intestinal parasites (*Ascaris*, hookworms, and *Strongyloides*), infecting larvae pass through the lungs, entering via the bloodstream, penetrating into

### Box 125-6 Pulmonary Eosinophilia

1. Drug- and toxin-induced eosinophilic lung diseases
2. Helminthic infection-related eosinophilic lung diseases  
Transpulmonary passage of larvae (Löffler's syndrome):  
*Ascaris*, hookworm, *Strongyloides*  
Pulmonary parenchymal invasion: mostly helminths, paragonimiasis, echinococcosis  
Heavy hematogenous seeding with helminths: trichinellosis, disseminated strongyloidiasis, cutaneous and visceral larva migrans, schistosomiasis  
Tropical pulmonary eosinophilia: filaria
3. Fungal-related eosinophilic lung diseases  
Allergic bronchopulmonary aspergillosis
4. Chronic eosinophilic pneumonia
5. Acute eosinophilic pneumonia
6. Churg-Strauss syndrome—vasculitis
7. Other: neoplasia, idiopathic hypereosinophilic syndrome, bronchocentric granulomatosis

Modified from Weller PF: Eosinophilia and eosinophil-related disorders. In Adkinson NF Jr, Yunginger JW, Busse WW, et al (eds): Allergy: Principles and Practice, 6th ed. St. Louis, Mosby-Year Book, 2003, p 1105.

alveoli, and then ascending the airway to transit down the esophagus into the small bowel. Löffler, who first described this syndrome of migratory pulmonary infiltrates and blood eosinophilia in Swiss patients, subsequently implicated *Ascaris* infection, acquired from the use of contaminated "nightsoil" (human excrement) as fertilizer, as the cause of this syndrome.<sup>85</sup> *Ascaris* is especially capable of eliciting eosinophilic inflammatory responses and is prevalent in regions where human feces contaminate soil or are used as fertilizer. Although infecting hookworm and *Strongyloides* larvae likewise traverse the lungs, these larvae rarely elicit symptoms of pulmonary eosinophilia in natural or experimental infections.<sup>86</sup>

Since Löffler's syndrome occurs only when developing larvae are transiting the lungs, about 9 to 12 days after ingestion of *Ascaris* eggs, this cause of pulmonary eosinophilia should be considered only in those with a recent exposure to *Ascaris* eggs (see Chapter 109). In symptomatic patients, common complaints are an irritating, nonproductive cough and burning substernal discomfort, and over half of patients have rales and wheezing. Acute symptoms generally subside within 5 to 10 days. Chest radiographs show unilateral or bilateral nonsegmental densities with indefinite borders ranging in size from several millimeters to several centimeters. Infiltrates are generally transient and migratory and clear over one or more weeks. Blood eosinophilia increases after several days of symptoms and resolves over many weeks. *Ascaris* pneumonia is diagnosed at the time of pneumonic involvement only by detecting *Ascaris* larvae in respiratory secretions or gastric aspirates.<sup>86</sup> At least 40 days must elapse before the larvae responsible for pulmonary infiltrates have matured sufficiently to produce eggs detectable in the stool. Negative stool examinations during or soon after an episode of pneumonitis do not exclude *Ascaris* as the cause nor do positive stool examinations for *Ascaris* eggs during the stage of pulmonary involvement establish the cause, as these eggs reflect infection acquired 2 to 24 months earlier.

## Pulmonary Parenchymal Invasion with Helminths

In contrast to the parasites mentioned previously that transit through the lungs, a few helminths, such as *Paragonimus* lung flukes (see Chapter 117) and echinococcal species (see Chapter 114), have a predilection to localize within the pulmonary parenchyma, and these may elicit eosinophil-enriched inflammatory reactions.<sup>86</sup> *Paragonimus* larvae undergo maturation in the lungs. Larval flukes can leave hemorrhagic, necrotic tracts; their eggs provoke a granulomatous response. Infection is endemic throughout much of Southeast Asia and is seen in the United States in immigrants from those areas. Because the chronic cavitary lesions of paragonimiasis can mimic tuberculosis, and many adults from Southeast Asia have positive tuberculin tests, patients may be misdiagnosed as having tuberculosis.<sup>87</sup> Echinococcal infection can also involve the lungs, though encysted parasites typically do not elicit a peripheral eosinophilia.

## Heavy Hematogenous Seeding with Helminths

This disease category includes the eosinophilic pulmonary responses elicited by helminthic larvae or eggs that are carried into the lungs hematogenously in an aberrant fashion. Thus, in contrast to the “normal” transpulmonary migration noted previously, etiologic helminths include abnormal numbers of nonhuman hookworms or ascarids causing cutaneous or visceral larva migrans,<sup>88,89</sup> abnormal numbers of hematogenous larvae in heavy trichinellosis infections,<sup>86</sup> and abnormal spread following chemotherapy of schistosomal parasites via collateral vessels into the lungs.<sup>86,90</sup> Also included in this category is disseminated strongyloidiasis, which develops when the *Strongyloides* autoinfection cycle becomes unbridled, often in association with corticosteroid or cytotoxic drug administration (see Chapter 111). Large numbers of larvae traverse the lungs eliciting pulmonary findings. Adult parasites can develop in the bronchial tree causing bronchospasm mimicking asthma.<sup>91</sup> In disseminated strongyloidiasis, filariform larvae can be found in many sites, including the stool, sputum, and bronchoalveolar washings. The usual eosinophilia of strongyloidiasis can be suppressed in disseminated disease because of concomitant pyogenic infection or steroid administration.

## Tropical Pulmonary Eosinophilia

This form of eosinophilic pneumonia results from a distinct immune response to the normally blood-borne microfilarial stages of lymphatic filariae, *Wuchereria bancrofti*, and, less commonly, *Brugia malayi* (see Chapter 98).<sup>92,93</sup> The disease is prevalent in regions where these filariae are endemic, and residents or immigrants from these regions are those who may experience tropical pulmonary eosinophilia. Males are affected more often than females in a ratio of about 4:1. Dyspnea, wheezing (especially at night), and chest discomfort may be accompanied by weight loss and malaise. Asthma may be the presenting complaint.<sup>94</sup> In addition to blood eosinophilia, features specific to tropical pulmonary eosinophilia include high levels of serum IgE and antifilarial antibodies. Bloodstream microfilariae are almost never found. Abnormalities on chest radiographs may be subtle and include diffuse miliary lesions 1 to 3 mm in size, patchy consolidations, cavitation, reticulonodular infiltrates of

the lower lung zones, and an interstitial nodular pattern.<sup>95</sup> Tropical pulmonary eosinophilia is an immunologically mediated disorder with microfilariae trapped in the lungs. Microfilariae are detected in inflammatory foci in biopsies from the lung, liver, and lymph nodes. A related, nonfilarial syndrome of tropical pulmonary eosinophilia of uncertain cause has been recognized.<sup>96</sup>

## Other Pulmonary Eosinophilias

At least 10 cases of severe acute pneumonitis with elevated eosinophils (peripheral and pulmonary) occurred in US military personnel deployed to Southwest Asia in 2003.<sup>97</sup> The etiology was not determined; an association with recent initiation of smoking was noted.

Among the drugs reported to cause pulmonary eosinophilia are ones sometimes taken for malaria prophylaxis and hence pertinent in patients who will have had tropical exposures. These include pyrimethamine and dapsone.<sup>98,99</sup>

Eosinophilic pleural effusions (Box 125-7) can have multiple causes.<sup>100</sup> In the setting of someone with potential infectious exposures, several helminthic infections, including toxocariasis,<sup>101</sup> tropical pulmonary eosinophilia,<sup>102</sup> paragonimiasis,<sup>103</sup> loiasis,<sup>104</sup> and anisakiasis,<sup>105</sup> can cause eosinophilic pleural effusions.

## Abdominal Pain or Diarrhea

The gut is the primary or sole residence in the human host for many helminthic parasites. Symptoms from these parasitic infections may result from several mechanisms, including attachment of the parasite to, or penetration of, the gut mucosa, causing irritation and inflammation; migration through the wall or to other adjacent sites (such as biliary and pancreatic ducts); intraluminal obstruction by a bolus of worms; and

 Periarteritis nodosa, especially Churg-Strauss syndrome  
 Regional enteritis  
 Ulcerative colitis  
 Lymphoma  
 Solid tumors  
 Drug reaction (e.g., eosinophilic colitis from naproxen)  
 Hypereosinophilic syndrome  
 Allergy (e.g., cow's milk, soy protein in infants)

entry into the appendix, among others. Helminths and other processes associated with eosinophilia and abdominal pain and diarrhea are listed in Box 125-8. The canine hookworm (*Ancylostoma caninum*) has been associated with a syndrome of abdominal pain, sometimes acute and severe, and peripheral eosinophilia.<sup>106</sup> The main pathologic finding is a focal or diffuse eosinophilic inflammation, which seems to be caused by a hypersensitivity response to secreted antigens from the canine hookworm. Larvae of the pinworm *Enterobius vermicularis* have also been reported to cause eosinophilic colitis and enteritis.<sup>107</sup> Helminth-elicited disease must be distinguished from often idiopathic eosinophilic gastroenteritis.<sup>108,109</sup>

**Skin**

Intermittent and migratory lesions of the skin and subcutaneous tissues can reflect migration of parasites in human tissues (see Chapter 126). Parasites associated with lesions of the skin and soft tissues are listed in Table 125-3. Skin lesions associated with gnathostomiasis (see Chapter 106) may begin as early as 3 to 4 weeks after ingestion of the parasite or may be delayed until months or even years later. The third-stage larvae cause localized swellings that typically last 1 to 2 weeks and are associated with edema, pain, itching, and variable erythema.

Swellings may recur off and on for 10 to 12 years. Because a single gnathostome can cause symptoms, cases have occurred after a brief stay in an endemic area or after eating foods, usually raw fish, from those areas. Disease has been most often reported from Southeast Asia. An increase in cases in Mexico, Peru, and Ecuador has been noted in recent years.<sup>110,111</sup> In addition to causing cutaneous disease, the worm can also migrate to tissues throughout the body, causing pulmonary, gastrointestinal, genitourinary, central nervous system (CNS), ocular, and other localized disease.<sup>50</sup> Loiasis, another disease causing migratory lesions and eosinophilia, follows exposures to *L. loa* in west-central Africa (see Chapter 99).<sup>61</sup> Symptoms typically do not appear until at least 4 months after exposure and can first appear more than 5 years after exposure. Classic findings are localized areas of angioedema (Calabar or fugitive swellings), which may be warm, red, itchy, or painful.<sup>28,52</sup> They usually disappear within a few days and may recur multiple times per year. Fever may accompany migration of worms. Worms migrating at a rate up to 1 cm per minute may be visible crossing the conjunctivae or bridge of the nose. Adult worms can survive more than 10 years.

A pruritic skin rash is a common feature of onchocerciasis (see Chapter 100). Swelling of an extremity should suggest obstruction of lymphatics caused by one of the filarial parasites. Patients may experience recurrent lymphangitis (often with retrograde progression) lasting 3 to 7 days, which may be associated with fever.<sup>77</sup> Orchitis and epididymitis are also characteristic features. Although eosinophilia can occur in patients with cutaneous larva migrans caused by the hookworm *Ancylostoma braziliense* and related nematodes, in one series only 20% had at least 7% blood eosinophilia.<sup>112</sup>

Penetration of schistosomal cercariae is typically followed by the development of an itchy, erythematous, papular rash.<sup>113</sup> Exposures to avian schistosomes elicit a similar skin reaction (swimmer's itch).<sup>113,114</sup> Skin biopsy is characterized by infiltration of eosinophils, though peripheral eosinophilia may be absent.

**Hepatobiliary**

Several parasites reside in the biliary tree and cause localized inflammatory changes and can obstruct the bile or pancreatic ducts leading to a clinical picture that can mimic acute cholangitis or cholecystitis (see Chapter 117). Other parasites, such as *Ascaris*, can wander from their usual habitat within the gut lumen to enter pancreatic or biliary ducts causing acute symptoms (see Chapter 109). In fascioliasis, the young fluke penetrates the capsule of the liver and migrates through liver parenchyma causing local necrosis and inflammation before it enters the bile ducts where it matures and produces eggs that are released into bile and passed in feces.<sup>115,116</sup> Eosinophilia may wax and wane when infection becomes chronic. Clonorchiasis, endemic in eastern and southeastern Asia, and opisthorchiasis, acquired mainly in Southeast Asia, are other parasites that reside in bile ducts (see Chapter 117). Among 17 immigrants who were found have ova of *Opisthorchis* spp. or *Clonorchis sinensis* in fecal specimens when evaluated in the US Midwest, 88% had eosinophilia (defined as absolute eosinophil counts  $>500/\mu\text{L}$ ). Clinical symptoms included vague right upper abdominal discomfort; 24% of those infected had been in the United States at least 5 years.<sup>117</sup> Other helminths as

**Table 125-3** *Helminths Associated with Eosinophilia and Skin and Soft Tissue Changes*

Parasite/Disease	Manifestation
Ascariasis	Urticaria
Coenurosis	Subcutaneous nodules, usually solitary
Cutaneous larva migrans*	Characteristic serpiginous lesions
Cysticercosis	Rubbery, painless cysts; often multiple
Dracunculiasis	Papules, vesicles; rupture and discharge larvae
Echinococcosis	Soft, subcutaneous cysts, varying sizes; urticaria
Fascioliasis	Urticaria; rare painful or itchy subcutaneous nodules
Filariasis	
<i>Brugia zoonotic filariae</i>	Local lymphadenopathy
Zoonotic dirofilariasis	Subcutaneous nodule
Loiasis	Pruritic 5–10-cm Calabar swellings; urticaria; papulovesicular lesions
Onchocerciasis	Subcutaneous nodules; papules and severe itching; urticaria; lizard skin
<i>Wuchereria bancrofti</i>	Recurrent retrograde lymphangitis and lymphadenitis; scrotal mass; hydrocele, elephantiasis
<i>Brugia malayi</i> , <i>Brugia timori</i>	Recurrent retrograde lymphangitis and lymphadenitis; scrotal mass; hydrocele, elephantiasis
Gnathostomiasis	Urticarial, edematous, recurrent, migratory subcutaneous swellings; creeping eruption; panniculitis
Hookworm	Urticaria; itchy maculopapular rash; may be vesicular
Paragonimiasis	Urticaria (early); subcutaneous nodules
Schistosomiasis	Urticaria, itchy maculopapules (early); papules (ectopic egg deposition)
Sparganosis	Edematous, painful migratory swellings secondary to worm migration
Strongyloidiasis	Itchy papular and migratory serpiginous lesions at points of penetration and dermal migration (larva currens); urticaria; papulovesicular lesions; petechiae and purpuric lesions in hyperinfection syndrome
Trichinellosis	Urticaria; periorbital edema; splinter hemorrhages
Visceral larva migrans	Urticaria; nodules

\*Eosinophilia usually low grade or absent.

well are associated with eosinophilia and hepatic dysfunction (Box 125-9).

### Fever

The clinical picture of undifferentiated fever and eosinophilia can be seen in acute schistosomiasis,<sup>39,118</sup> toxocaral visceral larva migrans,<sup>119</sup> trichinellosis,<sup>120</sup> fascioliasis,<sup>115</sup>

gnathostomiasis,<sup>50</sup> and some other parasitic infections.<sup>121</sup> In many instances, focal findings will develop (e.g., localized subcutaneous swellings, lymphangitis, cough and pulmonary infiltrates, abdominal pain, and others) that will give clues as to the organ systems involved. The combination of exposure history (when, where, and what activities) along with clinical findings can help the clinician to focus on more likely diagnoses. Box 125-10 lists helminthic infections causing eosinophilia and prominent fever.

### Box 125-9 Infections Causing Eosinophilia and Hepatic Dysfunction

- Angiostrongyliasis *cantonensis* (infrequent hepatic involvement)
- Ascariasis (mechanical obstruction of bile ducts by migrating worm)
- Capillariasis due to *Capillaria hepatica*
- Clonorchiasis
- Dicrocoeliasis
- Echinococcosis (eosinophilia may be absent with intact cysts; liver function may remain normal despite multiple cysts)
- Fascioliasis
- *Metorchis conjunctus*
- Opisthorchiasis
- Schistosomiasis
- Strongyloidiasis (with hyperinfection)
- Taeniasis (*Taenia saginata*; rare obstruction of bile ducts)
- Visceral larva migrans (toxocariasis)

### Central Nervous System Findings

Larvae of *Angiostrongylus cantonensis* migrate to the brain, spinal cord, and eye, where the larvae and young adults provoke an intense inflammatory response and cause the clinical picture of eosinophilic meningoencephalitis (see Chapter 105).

### Box 125-10 Helminthic Infections Causing Eosinophilia and Prominent Fever\*

- Clonorchiasis
- Fascioliasis
- Gnathostomiasis (early, episodic)
- Onchocerciasis
- Schistosomiasis (Katayama fever)
- Trichinellosis
- Visceral larva migrans (toxocariasis)

\*Acute, early ascaris, hookworm, or strongyloides may be associated with fever.

### Box 125-11 Causes of Eosinophilia in Cerebrospinal Fluid

#### Helminths

##### **Nematode (Roundworm) Infections with Migrating Larvae Inherently Neurotropic**

*Angiostrongylus cantonensis*  
*Gnathostoma spinigerum*  
*Baylisascaris procyonis*

##### **Cestode (Tapeworm) Infection with Cysts Developing in the CNS**

Cysticercosis  
 Echinococcosis  
 Coenurosis

##### **Trematode (Fluke) Infection with Ectopic CNS Localization**

*Paragonimus westermani*  
 Schistosomiasis  
 Fascioliasis

#### Miscellaneous Infectious Causes

Coccidioidomycosis  
*Cryptococcus neoformans*  
 Toxocariasis (*Toxocara canis*)  
 Trichinellosis  
 Myiasis (larvae of cattle botflies)

#### Noninfectious Causes

Ventriculoperitoneal shunts  
 Leukemia or lymphoma with CNS involvement (Hodgkin's)  
 Drug hypersensitivity reactions: nonsteroidal anti-inflammatory agents, antibiotics (e.g., sulfonamides, ciprofloxacin, vancomycin), phenytoin; myelography contrast agents  
 Idiopathic hypereosinophilic syndrome  
 Sarcoidosis

Although most cases and outbreaks have been reported from Southeast Asia and the Pacific basin, in 2000, 12 US travelers developed eosinophilic meningitis after travel to the Caribbean (Jamaica) where they had shared a meal.<sup>122</sup> Peripheral eosinophilia was present in 44% of patients on initial evaluation, though it eventually developed in all 9 who were hospitalized. A number of other parasites or their eggs can be associated with an eosinophilic tissue response and with variable eosinophils in the spinal fluid. Cysticercosis, which commonly involves the CNS, typically causes focal neurologic findings, including seizures (see Chapter 113). The cerebrospinal fluid (CSF) may be acellular and peripheral eosinophilia absent. In addition to helminthic parasites, other infections, drug reactions, and other processes can induce an eosinophilic meningitis<sup>123,124</sup> (Box 125-11).

### NONINFECTIOUS DISEASES

Many processes, as outlined in Box 125-1, are associated with eosinophilia and may need to be considered if helminthic infections do not explain a patient's eosinophilia. Because drug hypersensitivity reactions are relatively common, drugs should always be considered as a potential cause of eosinophilia even in persons who have visited or lived in

tropical regions (Box 125-12). The presence of a characteristic rash may suggest a hypersensitivity reaction, but drug-associated eosinophilia can occur in the absence of skin changes. In addition to peripheral eosinophilia, drug reactions may be associated with pathologic changes and dysfunction of other tissues and organs (Table 125-4). Any of these findings may predominate, or a combination of several may be seen at the same time or in staggered development. Rechallenge of patients with the drug may cause an accelerated reaction. Because of the striking blood or tissue eosinophilia, some drug reactions can mimic parasitic infections.

### EVALUATION OF PATIENTS WITH EOSINOPHILIA

Several key concepts are relevant to the evaluation of a patient with eosinophilia after tropical exposures:

- Multiple parasitic infections may be present.
- Excretion of eggs may be in small numbers or intermittent.
- Examination of stool for eggs is useless during the prepatent period. Symptoms such as fever and eosinophilia may be present for two weeks or more before the products of the adult parasite (e.g., eggs or larvae) are passed in the stool.
- Eosinophilia is most prominent with tissue-dwelling helminths, and many of these never enter the intestinal tract. Stool examinations will not detect tissue-dwelling helminths or exclude their presence as a cause of eosinophilia.
- Serologic tests may be negative early in the symptomatic period.

It is necessary to have some idea of the possible infections that might be present in order to focus the evaluation and determine which tests to do and which tissues to examine. Even if the patient is entirely asymptomatic and the physical examination is unremarkable, the presence of eosinophilia should lead to a workup to identify treatable diseases that could cause future problems. Eosinophilia, however, need not be present.<sup>59</sup> Knowledge of the geographic distribution of various parasites and the characteristic time interval between exposure and onset of symptoms and the presence of diagnostic forms of parasites or eggs in tissue or fluids is an essential part of the evaluation<sup>1</sup> (Box 125-13). For example, microfilariae of *W. bancrofti* will not be present on blood smears until about one year after exposure. A period of 4 to 6 weeks must pass after exposure to hookworm larvae before eggs can be found in the stool.

Whetham and colleagues outline a general strategy for evaluating returned tropical travelers with eosinophilia based on geographic areas.<sup>55</sup> They would do microscopic examinations of concentrated stool and *Strongyloides* culture and serology on all. For travelers to Africa, they would add schistosomal serology, terminal urine microscopy, and filarial serology. When travel or prior residence included West Africa, filtration and examination of blood for microfilaria was added. Whether skin snips were done depended on symptoms and filarial serology.<sup>55</sup>

Diagnosis of strongyloidiasis is often missed if the clinician relies on routine stool examinations. Although larvae can be found in stool samples, the sensitivity of the stool examination is low (see Chapter 111). In published series, estimates of positivity with a single stool examination range from 0% to 66%. Therefore, serologic tests that detect IgG antibodies to antigens of *Strongyloides* larvae are helpful in detecting strongyloidiasis.<sup>46,58</sup>

\*Reported to be associated with pulmonary changes.

Based on published reports and reports of adverse reactions to the Food and Drug Administration.

**Table 125-4** Examples of Drug-associated Reactions with Eosinophilia

Drug Reactions	Examples
Cytokine-mediated	GM-CSF, IL-2
Pulmonary infiltrates	NSAIDs
Pleuropulmonary	Dantrolene
Interstitial nephritis	Semisynthetic penicillins, cephalosporins
Necrotizing myocarditis	Ranitidine
Hepatitis	Semisynthetic penicillins, tetracyclines
Hypersensitivity vasculitis	Allopurinol, phenytoin
Gastroenterocolitis	NSAIDs
Asthma, nasal polyps	Aspirin
Pharmacologic	$\beta$ -Blockers
Eosinophilia-myalgia syndrome	L-Tryptophan contaminant
Asymptomatic	Ampicillin, penicillins, cephalosporins

GM-CSF, granulocyte-macrophage colony-stimulating factor; IL-2, interleukin-2, NSAIDs, nonsteroidal anti-inflammatory agents.

Modified from Weller PF: Eosinophilia and eosinophil-related disorders. In Adkinson NF Jr, Yunginger JW, Busse WW, et al (eds): Allergy: Principles and Practice, 6th ed. St. Louis, Mosby-Year Book, 2003, p. 1105.

Studies have reported sensitivities ranging from 80% to 90%. A study from London found serology was positive in 73% (22/30) of travelers and 98% (45/46) of immigrants with larvae found on stool examination.<sup>63</sup> In a study in Toronto of 76 patients with *Strongyloides* larvae found in fecal specimens, the *Strongyloides* enzyme immunoassay (EIA) done at the Centers for Disease Control and Prevention had a sensitivity of 94.5%.<sup>62</sup> Antibody titers declined slowly over many months after therapy.

**Timing of Tests**

Even when sensitive and specific serologic tests are available, they may be negative early in the course of infection. In a study of patients with acute schistosomiasis, serologic results were negative in 3 of 8 persons tested during the first week of illness.<sup>39</sup> If suspicion is high, serologic tests should be repeated if initially negative. During the prepatent period, serologic studies may be the only way to confirm the diagnosis.<sup>125</sup>

Timing of obtaining blood to search for microfilariae needs to be done cognizant of the potential periodicity exhibited by

**Box 125-13 Eggs or Parasites in Tissues or Fluids****In Urine**

Diectophymosis (eggs; rare infection)  
 Filariasis (microfilariae, e.g., *Wuchereria bancrofti*, *Loa loa*)  
 Gnathostomiasis (parasite passed in urine; rare)  
 Schistosome eggs (*Schistosoma haematobium*)  
 Strongyloidiasis (larvae, rare)

**In Sputum**

Ascariasis (larvae during early migration)  
 Echinococcosis (fragments of larvae and free scolices after rupture of cyst into bronchus; rare)  
 Gnathostomiasis (rarely coughed-up worm)  
 Hookworm (larvae, early)  
 Paragonimiasis (eggs in sputum)  
 Schistosomiasis (eggs)  
 Strongyloidiasis (filariform larvae, and rarely eggs and adults, in sputum in hyperinfection syndrome)

**In Pleural Fluid**

Paragonimiasis (eggs)  
 Strongyloidiasis (filariform larvae)

**On Blood Smears**

Microfilariae of filariasis (e.g., *W. bancrofti*, *Brugia malayi*, *L. loa*, *Mansonella perstans*, *Mansonella ozzardi*)  
 Trichinellosis (rarely observed on blood smears)

**In CSF**

Angiostrongyliasis due to *Angiostrongylus cantonensis* (larvae in CSF)

**On Perirectal Skin (Tape Test)**

Pinworm eggs  
 Tapeworm proglottids

**In Feces\***

Strongyloidiasis (20%–30% positive with a single examination; 60%–70% with three or more; 40%–90% positive on duodenal sample or endoscopic aspirate)  
 Several intestinal nematodes, trematodes, and cestodes

\*Eggs and parasites are not found in feces in patients with many helminthic infections, such as echinococcosis, toxocaral visceral larva migrans, and trichinellosis; stool examinations are often negative at the time of earliest symptoms in patients with many infections, including schistosomiasis, ascariasis, and hookworm infections.

the species and strains of filariae (see Chapters 98 and 99). In a study in Brazil, Dreyer and associates<sup>126</sup> found that microfilariae of *W. bancrofti* in both venous and capillary blood showed a nocturnal periodicity pattern, with the fewest microfilariae in the capillary bed of the skin when the biting activity of the local *Culex* vector was at its lowest level. Carriers with higher levels of microfilariae (at least one microfilaria per 20- or 60- $\mu$ L blood smear at night) could be identified during daytime hours by a filtration technique using 1 mL of venous blood. Routine blood films did not identify persons with low levels of parasitemia, even if done at night. Box 125-14 lists examples of useful diagnostic tissues to sample.

In general, it is preferable to diagnose infection by identification of eggs, larvae, adults, or other parasitic stages or products in tissues, fluids, or stool. Sometimes diagnostic

**Box 125-14 Identification of Parasite or Its Products by Morphology, Staining Characteristics, and Appearance**

- Skin biopsy: schistosome eggs
- Skin snips: microfilariae of *Onchocerca volvulus* and *Mansonella streptocerca*
- Rectal biopsy: for eggs of *Schistosoma japonicum*, *Schistosoma mansoni*
- Bladder biopsy: for eggs of *Schistosoma haematobium*
- Muscle biopsy: for *Trichinella* larvae
- Liver biopsy: larvae of *Toxocara*
- Excision of masses or biopsy of other tissues with pathologic changes (e.g., cysts or soft tissue masses caused by infections such as cysticercosis, gnathostomiasis, sparganosis, echinococcosis, others; filarial epididymal mass). In loiasis, the adult worm is found in subcutaneous tissue.

material is unavailable or its retrieval would entail serious risk to the patient (e.g., brain biopsy, liver biopsy, major surgical intervention). When parasites, eggs, or other products are unavailable, serologic tests are useful in some infections (Table 125-5). Problems with serologic tests may include lack of sensitivity, availability, standardization and quality control, and low specificity. Cross-reactivity to related parasites is common for many of the tests.

Acid-fast techniques stain schistosome eggs and hooklets of *Echinococcus granulosus*. Most helminths can be seen on hematoxylin and eosin-stained sections, but special stains, such as Weigert's iron hematoxylin or Russel-Moval pentachrome, can demonstrate the exoskeleton of helminths and improve visualization of characteristic morphology.<sup>127</sup>

**Table 125-5 Serologic Tests and What They Detect**

Infection	Serologic Tests Detect
Clonorchiasis	Antibody
Cysticercosis	Antibody, antigen
Echinococcosis	Antibody (can be negative even with established cysts), antigen
Fascioliasis	Antigen
Filariasis	Antibody, antigen
Gnathostomiasis (possibly useful)	Antibody
Onchocerciasis	Antigen
Paragonimiasis (possibly useful)	Antibody
Schistosomiasis	Antibody (IFA, IHA, ELISA), antigen
Strongyloidiasis	Antibody (ELISA IgG to <i>Strongyloides stercoralis</i> antigen, 80%–90%; IFA, up to 90%)
Toxocariasis	Antibody, antigen
Trichinellosis	Antibody (may not be positive to 3rd week of infection)

ELISA, enzyme-linked immunosorbent assay; IFA, indirect fluorescent antibody (test); IHA, indirect hemagglutination antibody (test).

## RESPONSE TO TREATMENT

Several key points should be kept in mind when treating patients with helminthic infections:

- Treatment may not be curative; efficacy may vary depending on the stage of the parasite.
- Symptoms may worsen, usually only transiently, with therapy.
- The level of eosinophilia may be a poor predictor of whether treatment has cured infection.
- Relapses can occur late.

Even when parasitic infections are recognized and treated, anthelmintic drugs may fail to cure infection. In a study of loiasis, 38% of patients were considered cured after a single course of diethylcarbamazine (DEC), increasing to 59% after one to three courses.<sup>128</sup> Although most relapses occurred within the first year after treatment, relapses occurring up to eight years after therapy have been reported, reflecting the long life span of the worms. Of 22 travelers treated for acute schistosomiasis after exposures in West Africa, eight still had evidence of active infection during 52 weeks of follow-up, though in two cases the possibility of reinfection could not be excluded.<sup>39</sup> Of 18 patients in Brazil with acute *Schistosoma mansoni* infection followed for two years, 14 (77.8%) were considered parasitologically cured. In that series, children had more intense clinical manifestations, were cured less often, and had slower resolution of symptoms than did adults.<sup>129</sup>

A temporary rise in eosinophilia after treatment has been observed in a number of helminthic infections.<sup>130,131</sup> The magnitude of the post-treatment eosinophilia correlates with the parasite burden prior to therapy.<sup>132</sup> This may be associated with other symptoms, such as pruritus, dermatitis, arthralgia,

and myalgia in patients with loiasis.<sup>128</sup> Patients with schistosomiasis may develop respiratory symptoms and new pulmonary infiltrates in association with therapy.<sup>90,131,132</sup> Severe symptoms have been reported when treatment is given early (during Katayama fever).<sup>130</sup> These worsening symptoms and the rise in eosinophils may reflect the host immune response to antigens released or exposed from dead or dying larvae or worms. In patients with loiasis treated with DEC, levels of eosinophils usually returned to normal within six months.<sup>128</sup> This occurred even in patients who had late relapses of infection.<sup>128</sup> Thus, normalization of levels of eosinophils after treatment does not necessarily indicate that infection has been eradicated. Conversely, however, the persistence of eosinophilia likely indicates that infections persist.

When ivermectin was used to treat 43 microfilaremic patients with bancroftian filariasis in Brazil, adverse clinical reactions, usually fever, headache, weakness, and myalgia, occurred in almost all patients but generally disappeared within 24 to 48 hours. Post-treatment eosinophilia was common and proportional to pretreatment microfilarial levels. After treatment, 38% of patients developed transient pulmonary dysfunction, 23% developed liver enzyme abnormalities, and 22% had hematuria.<sup>133</sup>

Timing of treatment may be important. Praziquantel, for example, is thought to be less active against the larval forms of schistosomes; schistosomes that have not reached the adult stage when treatment is given may survive.<sup>39</sup> Oral mebendazole, which is not well absorbed systemically, may have limited efficacy against developing hookworm larvae still in the lungs.

Box 125-15 outlines an approach to the evaluation of the patient with eosinophilia.

### Box 125-15 Evaluation of the Patient with Eosinophilia

#### **Eosinophil Determinations**

Confirm that the eosinophil count is elevated.

Estimate the absolute blood eosinophil count: normal,  $\leq 350$  eosinophils per  $\mu\text{L}$ ; elevated,  $>450$  eosinophils per  $\mu\text{L}$ .

Categorize eosinophilia as low ( $<1000/\mu\text{L}$ ), moderate ( $1000\text{--}3000/\mu\text{L}$ ), or high ( $>3000/\mu\text{L}$ ) (see Table 125-2)

#### **Medical History**

**Eosinophil history:** Inquire from history or medical records if eosinophil counts were previously normal or elevated, and if so for how long.

**Medication history:** Review drug exposure history for recent or current drugs that may be associated with eosinophilia. Discontinue any drugs that are commonly associated with eosinophilia and make a complete list of other medications, vitamins, supplements, or herbal preparations that the patient is taking. If patient is taking drugs that have been associated with eosinophilia, assess for associated serious organ involvement. Note any history of allergies to drugs or other agents.

**Disease history:** Review the medical history for diseases typically associated with eosinophilia (see Box 125-1). Given their prevalence, allergic and atopic disorders should be noted, although new onset of some allergic manifestations (e.g., urticaria [see Table 125-1], bronchospasm, wheezing) may be secondary to helminthic infections.

**Geographic history:** Review history of past residence and travel in other countries or regions. Relevant are time periods extending even decades before. Especially relevant are exposures in tropical regions and those with poor sanitation. Note places, dates, and duration of exposures. Some helminths have discrete geographic distributions (e.g., *Clonorchis* in the Far East; *Angiostrongylus cantonensis*, a cause of eosinophilic meningitis, principally, but not exclusively, in the Pacific Basin; *Loa loa* in central-west Africa; *Onchocerca volvulus* in equatorial Africa and elevated regions in Central America). Even nontropical geographic histories are relevant to some helminths and other agents, e.g., the southwestern United States for coccidioidomycosis. Exposures in sheep-rearing areas are pertinent to *Echinococcus granulosus*.

*Continued*

**Box 125-15** Evaluation of the Patient with Eosinophilia—Cont'd

**Activity history:** Review occupational and recreational exposures. Histories of swimming in or contact with freshwater in areas where schistosomiasis occurs are pertinent. Contact with fresh- or saltwater followed by a rash on water-exposed skin suggests schistosome dermatitis (avian schistosome species). Skin contact with soil potentially contaminated with human or dog feces, walking barefoot, or occupational (military or job-related) exposures, are pertinent to the acquisition of cutaneous larva migrans, hookworm, and *Strongyloides* infections.

**Dietary history:** Dietary histories are pertinent to several helminthic infections, including anisakiasis (raw fish), fish tapeworm (fish), *Nanophyetus salmincola* (salmon), *Taenia solium* (pork), *Taenia saginata* (beef), fascioliasis (watercress), fasciolopsiasis (water chestnut), gnathostomiasis (freshwater fish, eels, frogs, snakes, and poultry and pigs fed on fish), *Angiostrongylus cantonensis* (land snails or slugs, freshwater shrimp, crabs, some marine fish), and trichinosis (pork, boar, bear, horse, walrus, warthog).

**Other epidemiologic history:** Helpful in the evaluation is knowledge of whether the patient traveled with others and whether others developed similar illnesses—relevant to common-source water exposures (e.g., schistosomiasis) or food-borne illness (e.g., trichinellosis). In concert with geographic exposures, histories of exposures to insect vectors are pertinent (e.g., filarial infections).

**General history:** Do a careful review of systems for any current or recent symptoms, including a history of fevers (see Box 125-10), skin lesions (see Table 125-3) that may have cleared, and gastrointestinal illnesses (see Box 125-8).

**Physical Examination**

Do a careful physical examination paying close attention to skin and soft tissue for nodules or masses.

**Initial Laboratory Evaluation**

The presence of specific clinical symptoms and physical findings, as well as other information from the history, may begin to direct laboratory testing.

As needed, check routine studies to assess organ involvement (e.g., liver function tests, renal function tests, urinalysis, chest radiograph [CXR]).

**Further Diagnostic Evaluations**

Symptomatic patient with localizing findings: The evaluation will be guided by the nature of the historical information and results from the physical examination and initial laboratory tests based on the focal findings:

Skin: skin snips, skin biopsy, excision of mass

CNS: Computed tomography (CT) and magnetic resonance imaging (MRI); cerebrospinal fluid (CSF) examination (cell counts, differential, protein, glucose; larvae)

Pulmonary findings or abnormal CXR: sputum examination (routine, acid-fast bacteria, ova and parasites [O&P]), CT or MRI to better define lesions, including those not seen on CXR

Stool O&P; urine O&P; rectal biopsy, other tests (see Table 125-5; Boxes 125-13 and 125-14)

*Eosinophilia in a patient without other findings:*

Stools for O&P (×3 as needed)

*Strongyloides* serology (if stools negative); *Toxocara* serology

If exposures are relevant, check studies (Table 125-5; Boxes 125-13 and 125-14) for schistosomiasis, filariasis, onchocerciasis.

# Cutaneous Lesions

STEVEN D. MAWHORTER  
DAVID L. LONGWORTH

## INTRODUCTION

International travel exposes the traveler to a number of potential health risks. Although most visits to developing countries are uneventful, 15% to 37% of travelers experience some health concern, usually diarrhea.<sup>1,2</sup> Dermatoses occur in up to 12.4% of overseas travelers.<sup>1-3</sup> In nearly all surveys of returning travelers, skin lesions are one of the top five medical concerns.<sup>1-6</sup> The majority of lesions develop prior to return home and only rarely require hospitalization, although they often lead to medical evaluation.<sup>4-6</sup> The skin also represents the largest organ of the body and the most accessible to direct examination and observation. As a result, it is often a sentinel for many infectious diseases by being the primary site of involvement; the entry site of parasitic or bacterial pathogens; or by demonstrating lesions that result from toxin-, inflammatory-, or vascular-mediated changes associated with infection.<sup>7</sup>

Specific pathogens and the clinical manifestations of diseases commonly found in people residing in, or traveling to, tropical areas are discussed in detail elsewhere in this book. This chapter begins with a discussion of the pathophysiology of tropical and parasite-associated skin reactions, and then focuses on the approach to the patient who presents with cutaneous manifestations, to assist in the generation of a thoughtful differential diagnosis.

## THE SKIN AS TARGET ORGAN—PATHOGENETIC MECHANISMS

Although many pathogens can produce cutaneous manifestations, the skin has a limited number of responses to inflammatory or infectious processes. In general, the pathogenesis of skin manifestations of infectious diseases can be considered under six broad categories. The first category involves blood-borne dissemination of the actual infectious agent.<sup>8,9</sup> This category can be further subdivided into two areas based on whether the etiologic agent engages in direct interaction with the skin and dermal appendages to produce the cutaneous manifestations or mediates the interaction through cellular, humoral, or other immune mechanisms. Examples of organisms that directly involve the skin include *Neisseria meningitidis*, *Rickettsia* spp., endocarditis-related bacterial embolization (e.g., Janeway lesions and Osler's nodes), *Pseudomonas* spp. and other gram-negative ecthyma lesions, *Bacillus anthracis*, and *Candida* spp. In this setting, Gram's stain of the skin lesion may reveal the offending organism.<sup>10,11</sup>

Viral pathogens, such as varicella-zoster virus and many enteroviruses, may cause direct cutaneous findings following viremic seeding of the skin.<sup>9</sup>

Examples of immune reactions involving the skin to blood-borne organisms include *Salmonella* spp. (rose spots), *N. meningitidis* and *Neisseria gonorrhoeae*, measles, and rubella.<sup>9</sup> In these cases, cutaneous manifestations are typically due to local cutaneous immune vasculitis or dermal immune responses, including, but not limited to, immune complex deposition. Since the skin changes are largely immune complex mediated, direct smears of the lesions are much less likely to reveal a pathogen. Consistent with the bacteremic or viremic pathogenesis of this first category, many of the diseases associated with this mechanism of cutaneous involvement are often severe and occasionally life-threatening.<sup>9</sup>

The second category involves the local reaction to parasites that gain access to the body elsewhere and migrate to the skin but are not blood-borne. They can also elicit a direct or indirect immunologic response to produce the observed cutaneous changes. This category includes lymphatically borne agents such as the filarial parasites *Onchocerca volvulus* (onchocerciasis) and *Loa loa* (loiasis).<sup>12,13</sup> The nodules of both onchocerciasis and loiasis often contain adult worms (direct mechanism). However, generalized pruritus and maculopapular eruptions appear to be mediated by immune reactions to dermal-based microfilariae (indirect mechanism).<sup>14</sup> Other helminthic examples include the cutaneous nodules of *Dracunculus medinensis* (guinea worm) and *Spirometra* spp. (sparganosis).<sup>12,15</sup>

A third category involves the cutaneous immune reaction to direct penetration of the organism, which may or may not proceed to the further development of active deep-seated infection. Here, the examples are primarily parasitic, including human hookworm "ground itch," which occurs at the site of primary penetration.<sup>16</sup> When nonhuman helminths, such as feline or canine hookworms, penetrate the skin, they are unable to complete their life cycle. As a result, they persistently migrate through the epidermis with characteristic serpiginous tracks, called cutaneous larva migrans, created by the worm and the local host immune reaction. "Swimmer's itch," caused by avian schistosome cercariae penetrating the skin of sensitized people, is another example of an abortive helminthic infection.<sup>17,18</sup> The immunologic nature of the response (IgE-mediated histamine response in this case) is shown by the absent or minimal reaction in previously unexposed people.<sup>19,20</sup> Similar pruritic reactions occur in human schistosomiasis at the time of cercarial penetration, prior to the subsequent development of a productive infection.<sup>18</sup> Myiasis (see Plate 126-2C) and arthropod infestations, such as scabies and lice, are further examples in this category.<sup>21-24</sup> Arthropod bite and sting reactions are similar in that they usually represent a local immune reaction to deposited salivary contents that many vectors use to facilitate their blood meal. Mosquito saliva-specific IgE antibodies have been detected in humans after experimental bite exposure.<sup>25,26</sup> Although repetitive mosquito bites increase the chance of disease transmission, the actual immune reaction to mosquito bites is significantly diminished after repetitive heavy exposure, consistent with desensitization of IgE-mediated immune reactions.<sup>27</sup>

The fourth pathogenetic category involves dissemination to the skin of toxins produced by infectious agents.<sup>8</sup> The causative microorganisms are typically localized and distant

from the skin. Representative examples are toxic shock syndrome, streptococcal scarlet fever, and staphylococcal scalded skin syndrome.<sup>8,28</sup> Depending on the specific agent involved and the host response, diffuse erythema or vesiculobullous lesions can be seen. Significant hemodynamic instability is often produced by the toxins as well.

The fifth category relates to the mechanical disruption of normal cutaneous homeostatic mechanisms resulting in pathologic changes in the skin and its supporting structures. Lymphatic filariasis, with its inflammatory and physical distortion of the normal lymphatic structures, is a good example of this category.<sup>29,30</sup> The resulting lymphedema and increased susceptibility to infection both contribute to the skin changes that can occur over time. Similarly, lesions that form ulcers significantly increase the likelihood of secondary bacterial infection, usually prevented by an intact dermal–epidermal layer. This is often compounded by the limited hygiene available in many developing countries to both natives and travelers.

A sixth category is less well understood but involves an apparently systemic immunologic pathogenesis. Examples include erythema nodosum (Fig. 126-1), classic erythema multiforme, and Stevens-Johnson syndrome (referred to by some as erythema multiforme major or exudativum; Plate 126-1). In some cases of erythema multiforme, herpes simplex virus or *Mycoplasma pneumoniae* organisms have been found in the skin of such lesions, but most cases in this category do not show cutaneous antigen localization or toxin production.<sup>31–38</sup> Infectious, noninfectious, and idiopathic causes are seen in this category. Infectious agents associated with erythema nodosum (Box 126-1) and erythema multiforme (Box 126-2) include bacteria, mycobacteria, fungi, viruses, and helminths. In addition, most serious cutaneous manifestations due to medications are mediated through this mechanism.<sup>39–41</sup> This is especially important in the context of traveling patients since most have been given new medications for prophylactic or empiric use, and many take medications chronically.

Owing to the varied nature of medication-related cutaneous reactions, it is useful to consider drug reactions as a separate category, although some overlap exists with the aforementioned categories. A section has been included at the

end of this chapter to document the spectrum of cutaneous reactions reported with medications commonly prescribed for people traveling to developing or tropical countries.

### GENERAL APPROACH TO THE PATIENT

In approaching patients with rash and tropical exposure, there are three important steps to help define the diagnostic possibilities. First, the patient's general medical and exposure history needs to be obtained.<sup>42</sup> Second, the rash should be accurately defined based on morphology (e.g., macule, papule, vesicle, and nodule), location, and distribution.<sup>43,44</sup> Third, associated clinical information gathered from a complete medical history and physical examination needs to be integrated. Such information includes a medication list, any sensations associated with the rash, pigmentation, migratory nature, duration, and changes in the rash over time. Ancillary clinical information not directly related to the rash must also be considered,

including other organ system involvement and the results of laboratory tests.

Patients often present to health care providers with a specific rash, which provides a starting point for the evaluation and subsequent construction of the differential diagnosis.<sup>45,46</sup> The importance of careful characterization of the rash cannot be overemphasized. This chapter is organized to provide important general information regarding the evaluation of patients with rash who have international exposure and includes tables organized by the character of the specific lesion or primary associated symptom to facilitate the practical usefulness of the information. The primary focus is on parasite-associated skin conditions and those nonparasitic conditions that are more prevalent in tropical and subtropical climates. The reader is encouraged to refer to standard dermatology texts for additional information on rash-associated

disorders when tropical exposure is deemed to represent an incidental component of the medical history.<sup>47</sup> In addition, important ancillary information has been included in the expanded tables to allow for more rapid review of the differential diagnosis. Efforts have been made to include the most common and most differentiating information to facilitate diagnosis in individual cases. It is hoped that the information will help focus the subsequent evaluation. When the disease listed refers to another table, this indicates that the condition is less commonly associated with the specific dermatologic presentation covered in that table compared with the listings with full text.

Most of the tables based on presenting manifestation in this chapter (see Tables 126-6 and 126-8 to 126-11) include information about the geographic distribution of the disease entities. They also provide acquisition and incubation information together with parasite survival times to help assess which diagnoses fit the medical history of exposure. Common associated findings are included since cutaneous findings are often not the sole problem but, rather, one aspect of a multi-system disorder. The presence or absence of specific associated findings may also help the provider to focus further evaluation by knowing what other things to look for to rule in or rule out a specific diagnostic consideration. The additional information column is intended to comment on helpful details associated with a specific condition or unique findings that may lead to a diagnosis apart from other possibilities.

This chapter focuses on evaluation and the approach to patients with cutaneous manifestations of travel or tropically acquired conditions and does not include expanded information on the details of specific diseases. Common diseases found primarily in the developed world are often not included for the sake of focus and brevity. We have also left discussions of prognosis and treatment to the chapters in this book dealing with the various diseases.

**History**

A detailed history is the essential starting point in the evaluation of a patient with a skin rash or cutaneous lesion who has traveled abroad. Box 126-3 outlines important points to consider when performing a history in this setting. In broad terms, the history has three main components. First is information about the patient, second is information about the patient's exposure to possible pathogens, and third is a detailed history regarding the rash.<sup>47</sup> As a general rule, travel within the past 3 months is more likely to be relevant to the diagnosis of an acute illness than more remote travel.<sup>47,48</sup>

The age of the patient is important because it has implications regarding disease prevalence, vaccine status, and types of exposures. Moreover, the character of the rash produced by a pathogen may differ depending on the age of the patient. For example, congenital toxoplasmosis and adult-acquired toxoplasmosis have different skin manifestations when rash is present. The skin lesions of congenital disease are usually papular or hemorrhagic with occasional petechial, nodular, bullous, or erythrodermic changes.<sup>49</sup> In adult-acquired disease, rash is much less common, but when present it is frequently maculopapular with centripetal spread. Rare lichenoid, purpuric, vesiculobullous, and urticarial presentations have been described.<sup>50,51</sup>

### Box 126-3 Important Historical Aspects in the Traveler with Rash

#### Patient Demographics

Age  
Sex  
Occupation  
Reason for travel (vacation vs. business vs. other)  
Medications, allergies, immunizations  
Pretravel evaluation (compliance with pretravel recommendations?)  
Medical conditions that may alter immune status  
Time interval from travel dates to onset of symptoms

#### Exposure

Geographic location  
Description of location  
Duration of exposure  
Vector exposure (precautions taken?)  
Animal exposure (wild vs. domestic)  
List of items purchased (e.g., animal hide rugs, nickel-containing jewelry)  
Sexual contact with new partners  
Parenteral exposure (e.g., vaccine or injection abroad, acupuncture, tattoos, poultices on open sores)  
Immigrant?  
Country of origin  
Age on arrival in developed country  
Frequency and duration of return visits  
Rash-related information  
Prodromal symptoms  
Character  
Distribution  
Progression  
Speed  
Physical pattern  
Relation to fever  
Previous treatment and efficacy

The underlying immune status of the patient also has important implications regarding the differential diagnosis. Immunosuppressed travelers may be at increased risk of acquiring intestinal protozoa, including *Giardia lamblia*, *Isospora belli*, *Entamoeba histolytica*, and *Cryptosporidium parvum*.<sup>52,53</sup> Once infected, several reports document a more prolonged and more symptomatic infection in patients with altered cellular or humoral immunity.<sup>54–57</sup> Common organisms in the environment, such as *Candida* spp., *Cryptococcus neoformans*, *Pneumocystis carinii*, and *Mycobacterium tuberculosis*, are also a greater threat to travelers with weakened immune systems. Interestingly, there is little evidence that human immunodeficiency virus (HIV) infection increases the rate of helminthic infection or decreases the efficacy of treatment, with the limited exception of strongyloidiasis.<sup>58</sup> Immunosuppressed patients who have a history of international travel may have acquired long-lived and latent organisms such as toxoplasmosis that may lead to possible dissemination and symptomatic reactivation long after the time of travel.<sup>59,60</sup> Examples of other developing-world diseases with the potential for reactivation or dissemination include coccidioidomycosis, histoplasmosis,

hepatitis B, leishmaniasis, strongyloidiasis, and *Trypanosoma cruzi* infection.<sup>61</sup> In addition, the high prevalence and intrinsically persistent nature of members of the herpesvirus family (herpes simplex virus, cytomegalovirus, Epstein-Barr virus, and varicella-zoster virus) result in frequent reactivation during immunosuppression.<sup>62</sup> Herpesvirus reactivation may also be triggered by sun exposure and stress, both of which can increase with travel to developing countries.<sup>63</sup>

Current, chronic, and travel-related medication use and vaccine status are crucial demographic data that may help to reveal a cause (e.g., drug reaction) or tailor the differential diagnostic considerations for the traveler with a new rash. For example, in a patient with petechiae after travel to central Africa, the level of compliance with antimalarials or whether meningococcal vaccination was performed prior to travel can significantly influence the weighting of the considerations in the differential diagnosis.

Details related to the specific exposures of an individual patient are a crucial aspect of the history. Issues to elucidate include potential exposure to the etiologic agent directly, the vectors that may harbor the pathogen, and personal behavior(s) that alters the likelihood of exposure to a given agent. In most cases, these issues involve overlapping considerations, as discussed later.

The possibility of direct exposure is usually higher if travel includes significant rural exposure. A travel itinerary that includes only short stays in first-class hotels in major urban centers is less likely to result in the acquisition of a tropical disease than extended treks in underdeveloped areas of the country. However, the food preparer at a first-class resort may come from an impoverished area where hepatitis A is highly prevalent and may inadvertently contaminate the food prepared in such settings.<sup>64</sup>

Casual sexual contact is an example of potential direct exposure in which choice of protection use controls the relative risk of disease acquisition. Because sexually transmitted diseases (STDs) rank high on lists of disease prevalence in travelers, a sexual history is an essential part of the exposure evaluation.<sup>1,65</sup> Moreover, many STDs, such as primary HIV, secondary syphilis, and the group of genital ulcerative conditions, have prominent cutaneous findings (Table 126-1 and Plate 126-2D). A survey of malaria and sexual preventive measures found equivalent knowledge of the risks of malaria, HIV, and other STDs. However, whereas 87% of travelers adhered to malaria chemoprophylaxis recommendations, 50% of travelers engaged in casual sexual encounters abroad, with 38% of those unprotected.<sup>66</sup> Of note, those who engaged in high-risk sexual practices were not the same group that were noncompliant with malaria protective measures.

Vector exposure related to geography, types of vectors present, and intensity of exposure all need to be considered. Many tropical diseases have a very defined distribution, making geographic exposure very important. The risk of malaria and its pattern of drug resistance can vary greatly, even within a country such as Thailand or Kenya.<sup>67</sup> Malaria is uncommon in most urban centers, whereas yellow fever can be found there, reflective of the breeding patterns of the specific mosquito vectors transmitting malaria and yellow fever, respectively.<sup>68</sup> In addition to location, the duration and intensity of vector and pathogen exposure are also important. Some diseases, such as schistosomiasis, may be readily acquired after a single

exposure to an infected water source. Other diseases, such as malaria or lymphatic filariasis, usually require repetitive mosquito exposure since even in endemic areas the vast majority of mosquitoes are not infectious.<sup>69,70</sup> If closed shoes are consistently worn, the likelihood of acquiring cutaneous penetrating helminths, such as hookworm or *Strongyloides stercoralis*, is greatly reduced.<sup>16,71</sup>

Recent exposure is typically most important, especially exposure within the past 3 months. However, as noted in the tables, malaria, many helminths, and other tropically acquired pathogens can persist for months to years in the human host, requiring their consideration in selected clinical settings well beyond the actual time of travel.<sup>42</sup> In such cases, the presentation is typically subacute or chronic, although it may be punctuated by acute episodic illness. For example, vivax malaria has a typical incubation period of 2 weeks but may first present 8 months after leaving a malarious area. In addition, recrudescence may occur up to 5 years later in untreated patients.<sup>72</sup> Another example is lymphatic filariasis, which may have a relatively asymptomatic early phase but later can present with either subacute or chronic lymphedema or secondary cellulitis related to the disrupted lymphatics. The importance of understanding the life cycles of common parasitic pathogens and their impact on the patient's history is illustrated by *L. loa* infection. *Loa loa*-associated symptoms often require at least 6 months to appear and can first present as late as 18 months after the last possible exposure.<sup>73</sup> This is because microfilarial production typically takes 6 or more months to commence and the host immune response is primarily directed against the microfilariae rather than the adult worms. Adult worms in lymphatic filariasis and *L. loa* can persist for up to 10 years without reexposure.<sup>74</sup> Because of an autoinfective cycle, *S. stercoralis* infections acquired decades earlier can result in risk to people who require immunosuppression many years after their disease exposure and acquisition.<sup>75,76</sup>

Another exposure-related issue is whether the patient is a lifelong resident of a developed world country or has emigrated to a developed country recently or remotely. Expatriates are

much more likely to have an allergic or hypersensitivity form of *L. loa* infection compared to the local population.<sup>77</sup> The frequency and duration of return visits to tropical areas may be very important information in creating the proper differential diagnosis. Malaria may be significantly more severe in people who have returned to an endemic area after several years away. In addition, people traveling to visit family in developing countries may be less rigorous about seeking pretravel advice and using prophylactic medication, incorrectly believing that their prior exposures are protective. Rarely, the "traveler" may not be the index patient one is evaluating but, rather, a friend or worker who has significant contact with the patient. For example, reports of cysticercosis in Orthodox Jewish community members in New York who had not traveled outside the United States were associated with employing a housemaid or cook from endemic areas in Central America.<sup>78</sup>

The occupation of the traveler is an important aspect of the history as well. For example, development workers are much more likely to be exposed to soil-, water-, and arthropod-borne diseases than a businessperson with an urban itinerary. Compliance with preventive precaution instructions is important since proper use of protective footwear and avoiding swimming in areas endemic for schistosomiasis, for example, essentially rule out the disease as a diagnostic possibility. Animal exposure will help establish the relative risk of zoonoses for a particular patient.<sup>79</sup>

Questioning the patient about unusual situations or risky behaviors may uncover certain events, such as ingestion of raw seafood or questionable medical interventions, that are relevant. Acupuncture with unsterilized needles carries a risk of hepatitis and HIV transmission. A peculiar route of acquisition of sparganosis is seen when raw frog flesh is used as a poultice. Frogs can function as an intermediate host of this normally feline or canine tapeworm. The pathogen has worldwide distribution.<sup>15</sup> Physicians unaware of alternative medical practices of some immigrant populations usually do not consider such a route of exposure when obtaining a history. Asking about souvenirs purchased may reveal exposure to

animal products (e.g., animal skin rugs) that carry the risk of disease transmission, such as brucellosis or anthrax, or to new materials (e.g., nickel-containing jewelry) that can result in allergic contact skin reactions.<sup>80</sup>

Occasionally, the careful history may also help to point to an obsessional concern about the presence of parasites without other evidence to support such a diagnosis. Patients with this preoccupation often present to physicians with a variety of cutaneous lesions described as parasite “tracks” and may bring containers filled with “parasites.”<sup>81</sup> Many of these patients have attempted to extract the parasite themselves to present it to the physician. In reality, the dermatoses are self-inflicted injuries. Although cutaneous arthropod infestations can be protean in presentation and very challenging to diagnose, when faced with the presenting constellation noted previously, the possibility of delusional parasitosis should be considered.<sup>82,83</sup>

Specific questions about the rash and any associated clinical symptoms, such as fever pattern, weight loss, diarrhea, and response to treatment, if attempted, are also important for complete evaluation. The symptoms related to the rash may, at times, provide important diagnostic clues. For example, patients with myiasis, produced by cutaneous invasion by larvae of the botfly in Latin America or tumbu fly in Africa, often present with papules, nodules, and subcutaneous swellings and will frequently describe a sensation of movement and intermittent pain at the site of the lesion.

### Physical Examination

The physical examination is central to the evaluation of the patient with rash and tropical exposure. A complete examination is important since cutaneous manifestations may be only one component of a systemic disorder. Since the pattern of the rash may be important, the entire skin should be examined with attention to the elements listed in Box 126-4. Repeat examination over time may be necessary. The rapidity of spread can have implications regarding the aggressiveness of the evaluation. The general level of toxicity and the nature and tempo of the pattern of the rash dictate the initial evaluation and therapeutic approach. Although only 7% of cases with petechiae and fever will turn out to be meningococcemia,<sup>84</sup> the life-threatening nature of meningococcal disease requires an aggressive evaluation and often empirical therapy when this diagnosis is a consideration.<sup>7,8</sup>

The classification of the rash is often the focal entry point into the creation of a differential diagnosis.<sup>4-6</sup> As a result, the primary and secondary character of the rash should be carefully determined (see Box 126-4). Diagnostic considerations based on the information obtained are discussed under Characterizing the Rash. Some rashes are fleetingly present, such as *Salmonella* spp. rose spots. Other rashes may evolve in relatively unique patterns over time, such as anthrax, Rocky Mountain spotted fever (RMSF), and dengue.<sup>21,85-89</sup> Cutaneously acquired anthrax characteristically evolves from a papule to a vesicle with surrounding brawny, gelatinous edema, and occasional satellite vesicles<sup>85,86</sup> (Fig. 126-2). The lesion then progresses to hemorrhage and necrosis, eventually turning into an eschar. RMSF skin changes are often absent in the first few days of clinical illness. Then a macular rash typically starts on the wrists and ankles with centripetal spread.<sup>21</sup> During progression, the rash usually becomes petechial or purpuric or

### Box 126-4 Important Aspects of the Physical Examination in the Traveler with Rash

- Vital signs

  - Lymphadenopathy
  - Splenomegaly or hepatosplenomegaly

both (Fig. 126-3). Dengue fever rash often begins as a transient macular exanthem approximately 24 hours after the abrupt onset of fever. Three or 4 days later, a generalized maculopapular truncal rash appears, with centripetal spread, sparing the palms and soles (Fig. 126-4). This rash may become petechial and may even desquamate.<sup>87-89</sup>

The original and subsequent distribution of the rash, consideration of mucosal (enanthem) or genital involvement, and

**FIGURE 126-2** Cutaneous anthrax showing characteristic central eschar with surrounding edema and vesicles. (Courtesy of Kenneth J. Tomecki, MD, Cleveland, OH.)

**FIGURE 126-3** Early macular rash of Rocky Mountain spotted fever. Papular and petechial changes are often seen. The rash typically begins around the wrists and ankles.

other associated physical findings may be helpful in establishing a diagnosis. The presence of lymphadenopathy (Box 126-5) and splenomegaly or hepatosplenomegaly (Box 126-6) are examples of findings that may help focus the evaluation. If a primary lesion or an inoculation site can be determined, it should be given careful attention. For example, an eschar would indicate rickettsial disease or anthrax (Table 126-2), whereas periorbital swelling in a child soon after a visit to rural Brazil would focus the evaluation on Chagas' disease. The presence of a visible parasite at the site of the rash is also quite helpful in narrowing the differential diagnosis. For example, in some patients with myiasis who present with papular or nodular lesions that may resemble boils, a central opening termed a breathing pore is sometimes present from which larvae of the botfly or the tumbu fly may emerge. In some patients with dracunculiasis, the visible presence of the worm protruding from the skin establishes the diagnosis.

Patients with tungiasis, produced by the female jigger or sand flea, *Tunga penetrans*, often present with nodules on the feet with a central dark punctum, which represents the flea's posterior abdominal segments. Despite these examples in which the appearance of the rash can point to the diagnosis, the appearance of the rash is often not pathognomonic of a single disease entity.

### Characterizing the Rash

The careful identification of the primary and secondary character of the rash will facilitate the creation of a differential diagnosis, especially when integrated with the clinical history and other associated physical findings. After defining the rash, the reader should refer to the table related to that characteristic to help with diagnosing the individual patient. The role of tropical exposure is highlighted here.

Significant medical conditions with prominent cutaneous manifestations may be due to common pathogens with worldwide distribution despite exposure to specific tropical pathogens. For example, although petechiae in the recently returned febrile traveler may represent malaria, dengue, or even Lassa fever, it is still crucial to consider meningococemia, rickettsial disease, and other diagnoses. Table 126-3 identifies life-threatening diagnoses with cutaneous manifestations that are seen throughout the temperate and tropical world.<sup>7,8</sup>

### Hemorrhage and Petechiae

Hemorrhagic or petechial rashes (Table 126-4) must be considered of life-threatening importance and evaluated rapidly.<sup>7,8,21</sup> Although many nonlethal rashes have this presentation, it is difficult, if not impossible, to rule out serious pathogens at the initial evaluation. Worldwide, meningococemia is the most important cause of life-threatening disease presenting with fever and hemorrhage or petechiae. It is endemic in central Africa and sporadically epidemic in Brazil, India, Nepal, and Saudi Arabia (especially at the Hajj). Vaccination is available and efficacious.<sup>90</sup> Infection-mediated petechial or purpuric

lesions may arise directly from infected emboli or via an indirect immunologic mechanism. Thrombocytopenia from a variety of causes may also lead to purpuric or petechial lesions. Excellent data on the severity and mortality of severe adverse drug reactions, including hemorrhagic or petechial presentations, are found in a review.<sup>39</sup>

**Macules and Papules**

*Macules* are flat lesions with altered pigmentation less than 1 cm in size. A *patch* is a macule greater than 1 cm in diameter. A *papule* is a solid elevated lesion less than 1 cm, whereas a *plaque* is used to describe a similar lesion larger than 1 cm or a group of confluent papules.

In general, macules, papules, and maculopapular eruptions are the most common cutaneous manifestations of infectious diseases and imply an inflammatory response to the inciting pathogen. Viral and bacterial diseases are the most common causes (Table 126-5).<sup>91</sup> Some specific tropical bacterial and viral disorders associated with macular, papular, or maculopapular rashes include anthrax, bartonellosis (Fig. 126-5), brucellosis, glanders, leptospirosis, Lyme disease, melioidosis, plague, relapsing fever, *Rickettsia* infections (especially typhus

and trench fever), tularemia, yaws, meningococcemia, dengue, rat-bite fever, secondary syphilis, tuberculosis, and *Vibrio vulnificus* infection. Many other viral pathogens acquired in the tropics are commonly associated with maculopapular eruptions. Most of the viral hemorrhagic fevers progress from macular exanthems to a maculopapular form prior to developing a hemorrhagic appearance.<sup>87,89,92</sup> Although often unappreciated, the acute illness associated with HIV seroconversion may be accompanied by a transient maculopapular dermatitis in approximately 50% of patients.<sup>93,94</sup> Protozoan parasites rarely cause macular or papular rashes.

**Table 126-2** Diagnostic Considerations in the Traveler with an Eschar

Pathogen	Condition (Vector)
<i>Rickettsia africae</i>	African tick bite fever
<i>Rickettsia akari</i>	Rickettsialpox (mite)
<i>Rickettsia australis</i>	Queensland coastal fever (tick)
<i>Rickettsia conorii</i>	Mediterranean spotted fever (tick)
<i>Rickettsia sibirica</i>	North Asian tick typhus
<i>Rickettsia tsutsugamushi</i>	Scrub typhus (mite)
<i>Bacillus anthracis</i>	Anthrax*
<i>Loxosceles reclusa</i>	Brown recluse spider bite

\*Usually transmitted by contact with infected animals or their products, rarely mechanically via biting flies or insects.

**Table 126-3** Life-Threatening Conditions with Cutaneous Manifestations

Cutaneous Manifestation	Pathogen	Time to Appearance (after Onset of Illness)	Pathophysiology
Peripheral gangrene	Gram-negative bacteria	12–36 hr	Vascular thrombosis due to shock
Scattered, multiple petechiae and purpura	<i>Neisseria meningitidis</i> <i>Rickettsia rickettsii</i>	12–36 hr (later for <i>Rickettsia</i> )	Vascular invasion (?) Schwartzman reaction
Ecthyma gangrenosum	Gram-negative bacteria <i>Pseudomonas</i> spp.	Days	Vascular invasion, mostly venous
Asymmetrical scattered maculopapular rash	<i>N. meningitidis</i>	3–10 days	Immune vasculitis due to immune complex deposition
Polymorphous lesions	<i>Neisseria gonorrhoeae</i> <i>N. meningitidis</i> <i>N. gonorrhoeae</i> <i>Salmonella</i> spp.	3–10 days	Immune vasculitis
Rose spots	<i>Salmonella</i> spp.	5–10 days	Immune vasculitis
Osler's nodes; small (<1 cm) painful nodular erythema	<i>Staphylococcus aureus</i>	Days to weeks	Emboli from endocarditis with microabscesses
Janeway lesions: small or large (>1 cm) painless, purpuric or pustular, infarcted lesions	<i>Streptococcus</i> spp.	Days to weeks	Emboli from endocarditis
Diffuse toxic erythema	<i>S. aureus</i> <i>Streptococcus pyogenes</i>	Minutes	Vascular toxin with peripheral vasodilation
Macronodules	<i>Candida</i> spp.	Several days	Vascular invasion of dermis
Progressive petechiae and purpura (distinctive periumbilical purpura)	<i>Strongyloides stercoralis</i> (hyperinfection syndrome)	Hours to days from immunosuppression	? Larval skin penetration ? Immune vasculitis
Petechiae, purpura, hemorrhage	Viral hemorrhagic fevers	Within 3 wk of exposure	Immune vasculitis (disseminated intravascular coagulation) Thrombocytopenia Decreased clotting factor synthesis

The exceptions are toxoplasmosis, African trypanosomiasis, and some forms of both cutaneous and visceral leishmaniasis<sup>51,95–98</sup> (Fig. 126-6). Fungal infections usually manifest a nodular or ulcerative appearance (Plate 126-2E)<sup>99</sup>; however, coccidioidomycosis may have a maculopapular presentation.<sup>100</sup> Helminthic infections rarely have a papular or macular

appearance, although some forms of chronic onchocerciasis occasionally present this way.<sup>12,101,102</sup> Arthropod bites (e.g., mosquito bites) and infestations (e.g., scabies), together with water-related exposures to some diatoms, venomous fish, jellyfish, or sea urchins, commonly result in a toxin-mediated papular eruption.<sup>17,21,22</sup> This type of rash is also common in

**Table 126-4** Differential Diagnosis of a Petechial or Purpuric Rash after Travel or Tropical Exposure

Organism	Disease	Comment
<b>Bacteria</b>		
<i>Borrelia</i> spp.	Relapsing fever	
<i>Enterococcus</i> and viridans streptococci	Endocarditis	HACEK organisms as well
<i>Haemophilus influenzae</i> , <i>Haemophilus aegyptius</i>	Brazilian purpuric fever	Purulent conjunctivitis; mostly children ages 1–4 yr
<i>Leptospira interrogans</i>		
<i>Neisseria meningitidis</i>	Meningococcemia	
<i>Neisseria gonorrhoeae</i>	Gonococcemia	
<i>Burkholderia pseudomallei</i>	Melioidosis	
<i>Pseudomonas aeruginosa</i>	Ecthyma gangrenosum	
<i>Streptobacillus moniliformis</i>	Rat-bite fever	Different from <i>Spirillum minus</i>
<i>Treponema pallidum</i>	Syphilis (especially congenital)	
<i>Yersinia pestis</i>	Plague (septicemic)	“Black death” referred to purpura
<i>Rickettsia prowazekii</i>	Epidemic typhus	
<i>Rickettsia typhi</i>	Murine typhus	
<i>Rickettsia rickettsii</i>	Rocky Mountain spotted fever	Often on wrists and ankles
<i>Vibrio vulnificus</i>

the setting of drug hypersensitivity reactions.<sup>39</sup> Note that some arthropod bites/exposures may persist for weeks as immunologic reactions (e.g., papular urticaria) beyond the actual exposure, without indicating persistence of the organism. Fever is seen with many, although not all, skin reactions manifesting as macules or papules, possibly reflective of the systemic immune mechanism responsible for many maculopapular rashes.

### Migratory Rash

Migratory lesions are somewhat unique to parasites (Table 126-6). They represent a common cause of cutaneous lesions in travelers to tropical countries.<sup>5</sup> In some cases, such as cutaneous and visceral larva migrans,<sup>103</sup> humans are accidental hosts. The parasite is hence unable to complete its normal life cycle, resulting in continued wandering of the infecting larva through the skin.<sup>85</sup> Cutaneous larva migrans (CLM) (Fig. 126-7A and B) due to canine and feline hookworm species is the classic presentation; a differential diagnosis of this subset of migratory dermatoses is presented in Table 126-7.<sup>16,104–107</sup> Human hookworm (Fig. 126-7C) and strongyloidosis will occasionally manifest skin changes during initial or reinfective cutaneous penetration.<sup>16,104</sup> *Dracunculus medinensis* may produce superficial migratory skin lesions at the completion of its life cycle, prior to expulsion of the adult through the skin.<sup>12</sup> Parasite-associated eosinophilia is primarily related to the tissue migratory phase of the life cycle. As a result, parasitic

conditions characterized by migratory lesions often have an especially intense eosinophilia.<sup>108–110</sup> Lyme disease is a non-parasitic disease that may present with an expanding macular rash—erythema chronicum migrans.<sup>111</sup>

### Pruritus and Urticaria

A common manifestation of inflammatory skin conditions is pruritus (Table 126-8). Often, the inciting pathogen, drug, or irritant causes an immune response characterized by IgE production and subsequent histamine release by mast cells in sensitized people. As a result, pruritus is often accompanied by urticarial lesions. Classic syndromes include the intense itching seen following exposure to avian schistosome cercariae in IgE-sensitized people (swimmer's itch)<sup>17,18</sup> and the pruritic migratory angioedema seen with *L. loa* infections<sup>77</sup> (Fig. 126-8). Most helminthic parasites are capable of inducing an urticarial response, although it is uncommon. Helminthic infections in which humans are accidental hosts, such as CLM, gnathostomiasis, and sparganosis, are very likely to present this way due to the continued presence of the parasite in the skin. Human helminthic infections with cutaneous penetrating or cutaneous resident parasites, such as hookworm, strongyloidiasis, onchocerciasis, and loiasis, also frequently cause pruritus and urticaria. Hence, there is overlap with many of the migratory parasites. Some myiasis infestations are pruritic, especially when the larvae move.<sup>112,113</sup> Pruritus and/or urticaria are rare presentations of *Giardia lamblia*, but its worldwide distribution

**Table 126-5** Differential Diagnosis of Macular and Maculopapular Rashes after Travel or Tropical Exposure

Organism/Agent	Disease
Epstein-Barr virus	Mononucleosis
Dengue virus	Dengue fever*
Lassa fever virus	Lassa fever
Marburg virus	
West Nile virus	West Nile fever†
<i>Rickettsia typhi</i>	Endemic (murine) typhus
<i>Rickettsia prowazekii</i>	Epidemic (louse) typhus
<i>Rickettsia quintana</i>	Trench fever
<i>Coxiella burnetii</i>	Q fever
<i>Bacillus anthracis</i>	Anthrax*
<i>Spirillum minus</i>	Rat-bite fever
<i>Streptobacillus moniliformis</i>	Rat-bite fever
<i>Leptospira</i> spp.	Leptospirosis
<i>Yersinia pestis</i>	Plague
<i>Salmonella typhi</i>	Typhoid fever (rose spots)
<i>Borrelia burgdorferi</i>	Lyme disease
	Erythema chronica migrans
<i>Borrelia recurrentis</i>	Relapsing fever
<i>Bartonella bacilliformis</i>	Bartonellosis
<i>Brucella</i> spp.	Brucellosis
<i>Treponema pallidum</i>	Syphilis (secondary syphilis)
<i>Coccidioides immitis</i>	Coccidioidomycosis
<i>Toxoplasma gondii</i>	Toxoplasmosis
<i>Strongyloides stercoralis</i>	Strongyloidiasis
<i>Onchocerca volvulus</i>	Onchocerciasis
<i>Leishmania</i> spp.	Leishmaniasis (some visceral forms, rare cutaneous forms)
<i>Ancylostoma duodenale</i> and <i>Necator americanus</i>	Hookworm disease
Human immunodeficiency virus (HIV)	Primary HIV infection
Drug	

\*Only at onset; later, hemorrhage.  
†50% rash late in course of 3 to 6 day fever.

**FIGURE 126-5** Bacillary angiomatosis in a patient with HIV infection. Typical friable, exophytic papulonodular changes and violaceous hue are noted. (Courtesy of Karim A. Adal, MD, Minneapolis, MN.)

**FIGURE 126-6** Cutaneous leishmaniasis lesion demonstrating characteristic painless papular, nodular, and ulcerative lesions with serum crusting.

and relative prevalence reinforce the need for consideration of this parasite in the differential diagnosis. Humans have been shown to develop specific IgE antibodies to mosquito saliva and some people may benefit from prophylactic administration of antihistamines, resulting in less intense bite reactions.<sup>25</sup> Nonspecific skin inflammation can also result in pruritus in association with other lesions. Travelers to tropical climates may experience a noninfectious condition known as miliaria rubra (prickly heat) with characteristic itchy papules or vesicles on an erythematous base that are concentrated on the trunk and in flexure areas.<sup>99</sup>

### Nodules and Ulcers

A *nodule* is a palpable solid lesion greater than 0.5 to 1.0 cm in diameter. Nodules larger than 2.0 cm are classified as tumors. Most nodules are dermal in location, although occasionally they can arise from the epidermis (Table 126-9). Adult worms of *O. volvulus* typically reside in dermal lymphatics and develop into nodules due to chronic inflammation (Fig. 126-9).<sup>14</sup> Nodules are typically nearer the head in South and Central American disease, but they tend to involve the hips in African onchocerciasis. This difference in nodule location is attributable to preferred biting sites of the vectors. Some helminthic infections, such as dracunculiasis, need to leave the human host via the skin to complete their life cycle; hence, they form a nodule prior to extrusion.<sup>12</sup> In other examples, such as echinococcosis, CLM, sparganosis, and dirofilariasis, humans represent accidental intermediate hosts, which results in developmental arrest of the parasite at the larval stage, typically in skin or muscle tissue. An inflammatory nodule forms around the larva.<sup>114,115</sup> Humans can be the definitive (intestinal) and intermediate host (cysticercosis) for *Taenia solium*. In cysticercosis, subcutaneous nodules are occasionally part of the clinical manifestations.<sup>116</sup>

Although nodules and ulcers are separate dermatologic entities and can arise individually, there is often an association between the two lesions. In many cases, nodular lesions undergo eventual ulceration if the inflammatory process is intense enough to result in destruction of the overlying epidermis. *Ulcers* are defined as skin defects with loss of the epidermis and the

**Table 126-6 Differential Diagnosis of Migratory Skin Lesions**

Cause of Migratory Lesions	Distribution	Acquisition	Incubation	Parasite Survival	Common Associated Findings	Additional Information
Cutaneous larva migrans ("creeping eruption") Larval movement of zoonotic nematodes	Worldwide (especially tropics, subtropics)	Skin contact with contaminated soil (especially beaches)	Usually 2–3 days (range, 1–6 days)	Weeks to months	Transient eosinophilia; seriginous skin lesions can migrate up to several centimeters per day	Dog and cat hookworm; zoonotic <i>Strongyloides</i> ; humans incidental host; larvae cannot mature, wander in skin
Dracunculiasis Movement of adult worm just below dermis before eruption	Sub-Saharan Africa and India, Pakistan	Ingestion of copepod in drinking water	~1 yr	12–18 mo	Eosinophilia during tissue migration; can see dead calcified worms on radiograph	Adults exit via skin, blisters with eosinophils; rarely ulcerates; reinfection can occur
Fascioliasis Migratory inflammatory lesions	Worldwide except Oceania; sheep and cattle raising areas mostly	Ingestion of metacercariae on watercress or other in-water plants	3–4 mo	≥10 yr	Eosinophilia, abnormal LFT, anemia Early: fever, RUQ pain, jaundice, diarrhea, hepatomegaly Chronic: usually asymptomatic	Rare extrabiliary migration; nodules up to 6 cm; duodenal aspirate may help diagnosis; serology available
Gnathostomiasis Migratory inflammatory lesions	Asia (especially Thailand and Japan); sporadic worldwide	Ingestion of larva in undercooked or raw meat; ingestion of infected copepod in water; rare skin penetration	GI symptoms: 1–2 days; soft tissue swelling in 3–4 wk Other symptoms: months to years	≥10 yr	Eosinophilia common; can migrate anywhere, including CNS	Humans incidental host; larva cannot mature yet migrates in tissues, move 1 cm/hr, or faster when subcutaneous
Hookworm Larval movement during inoculation	Worldwide (especially tropics, subtropics)	Skin contact with contaminated soil	Local skin symptoms: 1–2 days Pulmonary symptoms: 1–3 wk GI symptoms: ~4 wk	<i>Ancylostoma duodenale</i> : 1 yr <i>Necator americanus</i> : 2–6 yr	Eosinophilia during tissue migration; anemia	Gross or occult blood in stools; eggs appear in 4–6 wk; rare reports of parasite survival for 15–20 yr (? hypobiosis of <i>A. duodenale</i> )
Loiasis Migratory inflammatory swellings	Central and West Africa	Bite of infected <i>Chrysops</i> fly	~1 yr (range, 4 mo–8 yr)	10 yr	Eosinophilia, increased IgE; expatriates have more hypersensitivity symptoms; microfilariae peak numbers in blood near noon	5–6 mo until microfilariae seen in blood; serology available

Table 126-6 Differential Diagnosis of Migratory Skin Lesions—Cont'd

Cause of Migratory Lesions	Distribution	Acquisition	Incubation	Parasite Survival	Common Associated Findings	Additional Information
Paragonimiasis Subcutaneous migratory swelling or subcutaneous nodules Sparganosis Larval movement	Sub-Saharan and southern Africa Americas: all except temperate climates; East and Southeast Asia Worldwide (especially tropics; most cases Southeast Asia)	Ingestion of metacercariae in raw or undercooked crustaceans  Ingestion of infected copepod in water; ingestion of raw or undercooked meat; use of infected flesh as poultice on open wound	Pulmonary symptoms: 6 mo CNS symptoms: 12–16 mo  Depends on route of acquisition	≤ 10 yr  ≥ 9 yr	Eosinophilia 80%; sputum may have Charcot-Leyden crystals; CXR can have almost any appearance (including 20% normal)  Eosinophilia and leukocytosis during migration	Eggs in sputum, feces, pleural or spinal fluid, first appear in 10 wk  Humans are incidental hosts, hence larva cannot mature; larva can migrate anywhere, including CNS
Strongyloidiasis ( <i>Strongyloides stercoralis</i> ) Migratory, serpiginous lesions of larva (larva currens)	Worldwide (especially tropics, subtropics)	Skin or mucous membrane contact with contaminated soil	Skin and pulmonary symptoms: days Other symptoms: days to decades	Indefinite (autoinfection possible)	Eosinophilia; skin changes (larva currens) common even in chronic infection; can migrate up to 5–10 cm/hr	Some institutions for mentally impaired may have high rates of infection; ex-POWs can carry asymptotically for decades
Myiasis Visible movement of maggot(s) or larva(e)	Worldwide (especially tropics)	Many mechanisms depending on fly species; contact with infected arthropods, vegetation, food, clothes; direct inoculation	Depends on fly: <i>Cordylobia anthropophaga</i> 7–10 days; <i>Dermatobia hominis</i> 5–12 wk	≥ 2 mo	Occasional eosinophilia; visible movement of maggot(s) within the lesion may be noted; larvae of some Diptera (e.g., <i>Hypoderma</i> ) migrate in soft tissues	Adult leaves host when mature

CNS, central nervous system; CXR, chest x-ray film; GI, gastrointestinal; LFT, liver function test(s); RUQ, right upper quadrant.

Table 126-7 Causes of Cutaneous Larva Migrans–like Rash

Pathogen	Condition	Usual Host
Common		
<i>Ancylostoma braziliense</i>	Cutaneous larva migrans	Dog and cat hookworm
<i>Ancylostoma caninum</i>		Dog hookworm
<i>Ancylostoma duodenale</i>	Ground itch	Human hookworm
<i>Necator americanus</i>		Human hookworm
<i>Strongyloides stercoralis</i>	Larva currens	Human nematode
Uncommon		
<i>Strongyloides myopotami</i>		Zoonotic <i>Strongyloides</i>
<i>Gnathostoma spinigerum</i>		Nematode of dog, cats
		Deep, broad tunnels
<i>Unicinaria stenocephala</i>		Hookworm of European dogs
<i>Bunostomum phlebotomum</i>		Hookworm of cattle
<i>Spirometra</i> sp.	Sparganosis	Tapeworm of dogs, cats
		More commonly visceral than cutaneous
<i>Spirurina</i> sp.	Creeping eruption	?Marine birds or mammals
		Raw fish, squid, shrimp, or turtles may transmit
		Thin, narrow tunnels
		Eosinophilia uncommon

Data from references 16, 104–107.

Typical distribution near the waistline is shown. C, “Ground itch” from an acute hookworm infection. (Courtesy of Richard Brown, MD, Democratic Republic of the Congo, and Richard L. Guerrant, MD, Charlottesville, VA.)

Table 126-8 Differential Diagnosis of Pruritic and Urticarial Skin Lesions

Cause of Pruritic Lesions	Distribution	Acquisition	Incubation	Organism Survival	Common Associated Findings	Additional Information
<b>Helminthic</b>						
Cercarial dermatitis; avian schistosome dermatitis	Worldwide (for all species salt- and freshwater)	Skin contact with cercariae in water	Hours	Unable to survive in human host		Avian and small mammal schistosomes; symptoms increase in severity with repeated exposure
Cutaneous larva migrans	See Table 126-6					
Dracunculiasis	See Table 126-6					
Gnathostomiasis	Asia (especially Thailand and Japan); sporadic worldwide	Ingestion of larva, undercooked or raw meat; ingestion of copepod in water; rare skin penetration	GI symptoms: 1–2 days; soft tissue swelling in 3–4 wk; other symptoms: months to years	≥10 yr	Eosinophilia common; can migrate anywhere, including CNS	Humans incidental host; larvae cannot mature yet migrate in tissues; move 1 cm/hr, or faster when subcutaneous
<b>Hookworm</b>						
Larval movement during inoculation	Worldwide (especially tropics, subtropics)	Skin contact with contaminated soil	Local skin symptoms: 1–2 days GI symptoms: ~4 wk Pulmonary symptoms: 1–3 wk (~1 yr (range, 4 mo–8 yr))	<i>Ancylostoma duodenale</i> : 1 yr <i>Necator americanus</i> : 2–6 yr	Eosinophilia during tissue migration; anemia	Gross or occult blood in stools; eggs appear in 4–6 wk; rare reports of parasite survival for 15–20 yr (? hypobiosis of <i>A. duodenale</i> )
<b>Loiasis</b>	Central and western Africa	Bite of infected <i>Chrysops</i> fly		10 yr	Eosinophilia, increased IgE; expatriates have more hypersensitivity symptoms; microfilariae peak numbers in blood near noon	5–6 mo until microfilariae seen in blood; serology available
<b>Onchocerciasis</b>	Sub-Saharan Africa, Mexico, Central and tropical South America, Yemen, Saudi Arabia	Bite of infected black fly	1–2 yr	Microfilariae: 2–3 yr Adult: 10–15 yr	Eosinophilia Skin nodules common Africa: mostly near hips South America: mostly near head	Microfilariae reside in skin; need skin snip to help diagnose; slitlamp may show microfilariae in anterior chamber of eye
<b>Pinworms</b> (“pruritus ani”) Adult worm movement near anus	Worldwide	Ingestion of infective eggs	4–6 wk	≥Months; autoreinfection common	Nocturnal perianal itching; eosinophilia only with rare tissue invasion; eggs in stool ≤5%; often no associated rash	Diagnosis by tape test; women may develop vulvovaginitis
<b>Schistosomiasis</b> (early)	Asia, Africa, Caribbean, tropical South America	Skin contact with cercariae in water	Skin symptoms: hours Katayama fever* 2–10 wk	3–10 yr	Eosinophilia early; hepatosplenomegaly with chronic infection	Consider rectal snip to diagnose if stool and urine for eggs negative; rare ectopic egg deposition to unusual locations, including CNS

Strongyloidiasis ( <i>Strongyloides stercoralis</i> ) Migratory, serpiginous lesions of larva (larva currens)	Worldwide (especially tropics, subtropics)	Skin or mucous membrane contact with contaminated soil	Skin and pulmonary symptoms: days Other symptoms: days to decades	Indefinite (autoreinfection possible)	Eosinophilia; skin changes (larva currens) common even in chronic infection; can migrate up to 5–10 cm/hr	Some institutions for mentally impaired may have high rates of infection; ex-POWs can carry asymptotically for decades
Trypanosomiasis, African	Sub-Saharan and southern Africa; scattered foci in east, central, and West Africa	Bite of infected tsetse fly	2–3 wk to fever	Years	Chancres at bite site starts in 2–3 days, lasts 2–4 wk; rash common, mostly on trunk; episodic/recurrent fevers last 1–6 days separated by weeks; generalized lymphadenopathy; anemia common; splenomegaly; chronic infection	Diagnosis difficult; elevated IgM seen in both serum and CSF when CNS involved; treatment toxic
Trichinellosis	Worldwide	Ingestion of raw or undercooked meat with larvae	10–20 days (range, 1–76 days)	Cysts viable in muscle 5–10 yr	1st week: diarrhea, abdominal pain, vomiting 2nd week: fever, myalgia, periorbital edema, marked eosinophilia CNS involvement 10%–20%	Antibody level low before 3rd week, then helpful; encysted larvae do <i>not</i> cause symptoms; humans are incidental host; most cases asymptomatic; smoking, salting, drying meat does not kill larvae
<b>Protozoan</b> Amebiasis	Worldwide	Cyst ingestion of fecally contaminated food or water	1–3 wk (range, 3 days–months)	Months		Rare presentation
Giardiasis	Worldwide	Cyst ingestion of fecally contaminated food or water; as few as 10 cysts can produce infection	1–3 wk (range, 1 day–6 wk)	Weeks–months	Malabsorption symptoms predominate; self-limited diarrhea; occasional chronic GI symptoms; increased in patients with immunodeficiency, especially hypogammaglobulinemia	Rare presentation: stool examination difficult; stool antigen test good sensitivity; most common cause of chronic diarrhea after travel; survives up to 2–3 mo in cool weather
<b>Bacterial</b> Relapsing fevers ( <i>Borrelia</i> spp. infections)	Louse: Africa, South America, Asia Tick: worldwide except Caribbean and Oceania	Contact with infected louse (hemolymph of crushed louse); tick bite	7–8 days (range, 2–18 days)	Months	Relapsing fevers last 4–10 days separated by approximately 1 wk; relapses milder Louse: 1–5 relapses (mean, 1) Tick: 1–13 relapses (mean, 3)	Louse: case fatality in epidemics 40% Louse and tick: mortality with treatment 2%–5%

Table 126-8 Differential Diagnosis of Pruritic and Urticarial Skin Lesions—Cont'd

Cause of Pruritic Lesions	Distribution	Acquisition	Incubation	Organism Survival	Common Associated Findings	Additional Information
Pinta	Central and South America	Close contact with an infected person	7–21 days (range, 8–60 days)	≥10 yr	Slowly enlarging papules over weeks to months; often see regional lymphadenopathy; papulosquamous rash 3–12 mo later with generalized lymphadenopathy; depigmented macules seen months to years later with atrophic scars	50% of infections subclinical; VDRL and FTA-ABS used as with syphilis
Typhus fever ( <i>Rickettsia prowazekii</i> )	Worldwide	Infected louse feces enter mucosal surface or break in skin	10–14 days (range, 5–23 days)	Lifetime of host	Characteristic symptoms: fever; severe headache, myalgias; fever lasts 8–20 days untreated; rash (maculopapular) starts on trunk on day 4–7, spreads to extremities	Infection occurs in endothelial cells→ widespread vasculitis; Brill-Zinsser disease (recrudescence infection): Milder symptoms Fever 7–12 days Much less rash Serology available Protean manifestations; HIV infection may affect serology; can be transmitted by blood transfusion
Secondary syphilis	Worldwide	Direct contact with infectious lesions; usually sexually transmitted	2–4 wk from onset of primary lesion (range, 10 days–years)	Lifetime of host	Chancre early; skin and mucous membrane lesions appear weeks to months later	Can cause false-positive VDRL; organism best seen by darkfield examination; animal inoculation most sensitive test
Rat-bite fever ( <i>Spirillum minus</i> )	Worldwide	Bite or close contact with infected rat	1–3 wk (range, 5–40 days)	Months	Bite site heals, then suppurates/ulcerates; rash in 75%, most prominent near bite, reddish brown to purple	Fleas infectious for months; can contact disease without travel; hunting and skinning animals a risk
Plague	Worldwide except Australia	Bite of infected flea or infected animal; inhalation of fomites from an infected patient	2–3 days pneumonic, 2–7 days bubonic (range, 1–14 days)	No long-term carriage	Abrupt onset of fever, chills, headache, and GI symptoms; hours later buboes form (no buboes if septicemic form); WBC may reach 50,000; CXR shows diffuse interstitial infiltrate; infarcts, hemorrhagic and necrotic nodules common	
<b>Viral</b> Hepatitis B	Worldwide	Sexual and intimate contact; blood and blood-contaminated objects (e.g., needles); mucous membrane contact with infected material; transplacental	2–3 mo	Usually weeks; uncommon chronic carriage	Usually asymptomatic; jaundice, anorexia, diarrhea; 5%–10% of cases show urticarial rash with arthralgia or arthritis	Chronic infection increases risk of hepatocellular cancer; vaccine safe and effective

Arthropod Bite and Infestations		Deposition of eggs directly, or via arthropod or inanimate vector	Days—weeks	2 mo; larvae leave host when adult	Local swelling and redness; occasional secondary bacterial infection	Some forms cause local tissue necrosis
Myiasis (Diptera fly larva)	Worldwide					
Tungiasis ( <i>Tunga penetrans</i> )	Tropical Central and South America, Caribbean, Africa, Asia (including India)	Skin penetration by larva of female sand flea	8–12 days	Up to 1 mo (flea dies after laying eggs)	Local pain and swelling usually on feet; tiny black spot at site of penetration	Inflammatory reaction to dead flea can persist; can result in tetanus and (rarely) gas gangrene
Fleas	Worldwide	Flea bite (usually unnoticed)	Hours—days	NA	Urticarial papules; papulovesicles/bullae (can persist days to weeks)	Skin lesions often found in clusters
Lice ( <i>Pediculus humanus</i> , <i>Phthirus pubis</i> )	Worldwide	Close physical contact with infected person	Days—weeks	Months <sup>†</sup> (life cycle: 3–4 wk)	Papular urticaria; nits (eggs) found on hair shaft; excoriations common; blue-gray macules at bite site	Shaving affected area may facilitate treatment
Mosquitoes	Worldwide	Bite of female mosquito	Immediate and 24 hr	NA	Immediate wheal (IgE + histamine-mediated); delayed (24 hr) papule	Repeated exposure alters cutaneous response
Bedbugs	Worldwide	Bite of <i>Cimex lectularius</i>	Hours	NA	Papular urticaria	Walls of mud homes
Kissing bugs	South America	Bite of <i>Triatoma sanguisuga</i>	Hours	NA	Papular urticaria; occasional nodular lesion	Hypersensitivity to mite and mite products; nodules often need steroid injections to heal
Scabies	Worldwide	Skin-to-skin contact with infected person; scabies mite acquisition from infected source (live 2 days on clothing/bedding)	Primary infection: 1 mo Repeat infection: hours—days	Months <sup>†</sup> (life cycle: 3–4 wk)	Severe generalized pruritus; burrows; occasional vesicles or nodules	
Tick granuloma	Worldwide	Bite of uninfected tick	Few hours	NA	After removal of tick a pruritic, red, papule/plaque seen; lasts 1–2 wk; occasionally firm nodule “tick granuloma” seen	At times need intralesional steroid or surgery for relief of pruritus

CNS, central nervous system; CSF, cerebrospinal fluid; CXR, chest x-ray film; FTA-ABS, fluorescent treponemal antibody absorption (test); GI, gastrointestinal; HIV, human immunodeficiency virus; NA, not available; VDRL, Venereal Disease Research Laboratories; WBC, white blood cells.

\*Katayama fever is characterized by fever, chills, cough, malaise, hepatosplenomegaly, diarrhea, eosinophilia, occasional urticaria, and lymphadenopathy. Symptoms last days to 3–4 months.

<sup>†</sup>Symptoms persist from reinfection until treatment given.

**FIGURE 126-8** Calibar swelling in the left (upper) forearm of an expatriate patient with loiasis. Eosinophilia of 60% was coincident with this rash.

papillary layer of the dermis (Table 126-10; Plates 126-2A and 126-2B). Although ulcers often develop from nodules, the reverse is rarely ever seen. Fungal skin lesions are typical of infections that show a spectrum of nodular and ulcerative presentations and hence are listed in a separate table<sup>98,117</sup> (Table 126-11). The time sequence of fungal skin lesions is indicated in Table 126-11 by the designation *I* for initial lesions and *S* for secondary ulceration. Anthrax, cutaneous leishmaniasis, and cutaneous mycobacterial diseases (*M. marinum* and *M. ulcerans*) are typical examples of lesions that progress through a nodular phase to develop ulcers in most patients<sup>85,118–120</sup> (Fig. 126-10). Chancroid and syphilitic chancres are examples of lesions that directly develop painless ulcers, without a primary nodular phase. Tularemia also presents with an ulcer at the inoculation site, which typically is intensely painful. Because *Francisella tularensis* can survive prolonged freezing, it is possible that imported meat may result in an infection distant in time and place from the source.<sup>121</sup>

When pyoderma gangrenosum is the leading diagnostic consideration for an ulcerative lesion, it is important to consider infectious etiologies. Travel-related possibilities include deep fungal infections, herpes simplex type 2, cutaneous tuberculosis, amebiasis cutis, and brown recluse spider bites.

**FIGURE 126-9** Onchocercal dermatitis demonstrating characteristic pruritic papules due to cutaneous microfilaria.

**FIGURE 126-10** A, Sporotrichoid rash of *Mycobacterium marinum* infection showing typical location on the superficial cooler body tissues of the extremities. B, A similar rash in a patient with classical sporotrichosis due to the fungal pathogen *Sporothrix schenckii*.

## Cysts

Cysts are similar to nodules but contain fluid. Overall, nodules are much more common than true cysts among tropical-associated infections. In echinococcosis and coenurosis, a true cyst is formed as part of the developmental process of the parasite. However, cutaneous and subcutaneous disease is rare with both of these infections. Some patients with *Gnathostoma spinigerum* form cysts around the parasite as part of the host immune response.<sup>105</sup> Among the filarial parasites, loiasis and onchocerciasis have skin nodules that harbor the adult parasites and occasionally appear cystic due to fluid accumulation around the nodule. Lymphatic filariasis occasionally results in lymphatic obstruction of the scrotal lymphatics in men, resulting in the development of a cystic hydrocele as the presenting manifestation.<sup>122</sup>

## Vesicles

There are three broad categories of vesicular lesions (Table 126-12). The first and most common is single or localized lesions.<sup>9</sup> An example is anthrax, with its evolving cutaneous lesion from painless papule to ulcer with surrounding vesicles. Other examples include herpes simplex and varicella-zoster, contagious ecthyma (orf and parapoxvirus), milker's

Table 126-9 Differential Diagnosis of Nodular Skin Lesions

Cause of Nodular Lesions	Distribution	Acquisition	Incubation	Organism Survival	Common Associated Findings	Additional Information
Helminthic Coenurosis	North America, South America, Europe, Africa, Asia	Ingestion of eggs in food, water, or on feces; contaminated hands	Months	≥15 yr	Usually no eosinophilia; neurologic symptoms if CNS involved; painless mass lesion ~2–6 cm cyst	Very rare infection, <100 cases reported; hematogenous spread before encystment
Cysticercosis Cysts, may be multiple	Worldwide	Ingestion of eggs in food, water, or on feces; contaminated hands	2 yr to onset of symptoms (range, months–30 yr)	10–15 yr	Usually no eosinophilia; abnormal head CT with cysts + multiple punctate calcifications; 25%–53% have intestinal <i>Taenia solium</i>	Symptoms can start after parasite dead; human is incidental host in this form of <i>T. solium</i> infection
Dirofilariasis	Worldwide (rare in Africa)	Bite of infected mosquito	2–3 mo	Months–years	No symptoms; rare hemoptysis; occasional subcutaneous nodules; coil lesion on CXR	Human is incidental host
Dracunculiasis Movement of adult worm just below dermis before eruption	Sub-Saharan Africa and India and Pakistan	Ingestion of copepod in drinking water	~1 yr	12–18 mo	Eosinophilia during tissue migration; can see dead calcified worms on radiograph	Adults exit via skin; blister with eosinophils, rarely ulcerates; reinfection can occur
Echinococcosis	Worldwide ( <i>Echinococcus multilocularis</i> ) Northern Hemisphere only)	Ingestion of eggs with food, fluid, or on fingers	Few years	Up to lifetime of host	Eosinophilia <35%; cyst wall may be calcified; liver > lung disease; symptoms due to mass effect or immune reaction	Humans are incidental intermediate host; hematogenous and lymphatic dissemination; serology available often negative with lung inf.
Filariasis ( <i>Wuchereria bancrofti</i> ; <i>Brugia malayi</i> ) Mass in scrotum	<i>W. bancrofti</i> : tropics and subtropics of Africa, Asia, Pacific islands, Central and South America, Caribbean <i>B. malayi</i> : South and East Asia	Bite of infected mosquito	5–18 mo	8–10 yr	Hydrocele (scrotal mass); lymphedema, elephantiasis, eosinophilia and increased IgE; microfilariae in blood peak near midnight	Rare tropical pulmonary eosinophilia syndrome (1%), serology available
Gnathostomiasis Migratory inflammatory lesions	Asia (especially Thailand and Japan); sporadic worldwide	Ingestion of larva or undercooked or raw meat; ingestion of copepod in water; rare skin penetration	GI symptoms: 1–2 days Soft tissue swelling in 3–4 wk; other symptoms months to years	≥10 yr	Eosinophilia common; can migrate anywhere, including CNS	Humans incidental host; larvae cannot mature yet migrate in tissues, move 1 cm/hr, or faster when subcutaneous
Loiasis Migratory inflammatory swellings	Central and western Africa	Bite of infected <i>Chrysops</i> fly	~1 yr (range, 4 mo–8yr)	10 yr	Eosinophilia, increased IgE, expatriates have more hypersensitivity symptoms; microfilariae peak in blood near noon	5–6 mo until microfilariae seen in blood; serology available

Table 126-9 Differential Diagnosis of Nodular Skin Lesions—Cont'd

Cause of Nodular Lesions	Distribution	Acquisition	Incubation	Organism Survival	Common Associated Findings	Additional Information
Onchocerciasis Severe, persistent pruritus	Sub-Saharan Africa, Mexico, Central and tropical South America, Yemen, Saudi Arabia	Bite of infected black fly	1–2 yr	Microfilariae: 2–3 yr Adult: 10–15 yr	Eosinophilia Skin nodules common: Africa: mostly near hips South America: mostly near head	Microfilariae reside in skin; need skin snip to help diagnosis; slit lamp may show microfilariae in anterior chamber of eye
Paragonimiasis Subcutaneous migratory swelling or subcutaneous nodules	Africa: Sub-Saharan and southern Americas: All except temperate climates East and Southeast Asia	Ingestion of metacercariae in raw or undercooked crustaceans	Pulmonary symptoms: 6 mo CNS symptoms: 12–16 mo	≤10 yr	Eosinophilia 80%; sputum may have Charcot–Leyden crystals; CXR can have almost any appearance (including 20% normal)	Eggs in sputum, feces, pleural or spinal fluid first appear in 10 wk
Schistosomiasis (early)	Asia, Africa, Caribbean + tropical South America	Skin contact with cercariae in water	Skin symptoms: hours Katayama fever*: 2–10 wk	3–10 yr	Eosinophilia early; HSM with chronic infection	Consider rectal snip to diagnose if stool and urine for eggs negative; rare ectopic egg deposition to unusual locations, including CNS
Sparganosis Larval movement	Worldwide (especially tropics; most cases Southeast Asia)	Ingestion of infected copepod in water; ingestion in raw or undercooked meat; use of infected flesh as poultice on an open wound	Depends on route of acquisition	≥9 yr	Eosinophilia and leukocytosis during migration	Humans are incidental hosts, hence larva cannot mature; larva can migrate anywhere, including CNS
Visceral larva migrans Due to <i>Toxocara canis</i> and other nematodes	Worldwide (need contact between human and dogs)	Ingestion of embryonated eggs from contaminated soil	≥1 mo (range, weeks–years)	10 yr	Eosinophilia: marked persistent Leukocytosis; fever, cough, wheeze, myalgia, abdominal pain, tender hepatomegaly CXR infiltrate 4%–33%	Serology available Eye disease uncommon: No eosinophilia Causes focal eye symptoms
Protozoan Amebiasis, cutaneous	Worldwide	Cyst ingestion in fecally contaminated food or water; uncommon sexual transmission	1–3 wk (range 2 days–months)	Months–years	Mucous membrane lesions of vagina, anus, or penis similar to carcinomas; cutaneous amebiasis is rare; painful granulation tissue or ulcers on presentation	Cysts can remain viable in environment up to 2 mo
Leishmaniasis, cutaneous and mucocutaneous	Scattered: Africa, South and Central America, Caribbean, Asia (middle and western, central and southern), U.S.–Mexico border	Infected sandfly bite	Weeks–2 mo; strain-dependent; may take months to years for correct diagnosis	Months–years	Papule → nodule with central crust; crust falls off to reveal painless ulcer with raised border; heals slowly with scar; single lesion to cluster to widespread	Presentation varies from self-limited to disfiguring; infection can be subacute, chronic, or relapsing; biopsy best diagnostic

Leishmaniasis, visceral	Africa, Mexico, South and Central America, Mediterranean area, Asia	Infected sandfly bite; rare blood transfusion	2–6 mo (range, 10 days–1 yr)	Years	<p>papules, nodules, plaques: mucocutaneous more ulcerative and erosive; cutaneous more nodular</p> <p>Bite papule/nodule may persist for months; insidious onset of fever, malaise, weight loss, and sweats; diarrhea and cough may be prominent; nontender HSM and LN seen; post kala-azar dermal disease (<math>\leq 20\%</math>) starts 1–20 yr after apparent cure, as nodular infiltration of skin</p>	<p>test—need to suspect or easy to miss</p> <p>Can see profound decrease in CD4 T cells without HIV; serology can be helpful, but often negative if also HIV-infected</p>
Trypanosomiasis, African	Africa, East, Central, West	Bite of infected tsetse fly	2–3 wk (range, 2 days–months)	Years	<p>Bite “chancere”; starts 2–3 days after bite; lasts 2–4 wk; red/purple, indurated several centimeters in diameter; painless to tender; lymphadenopathy common (posterior cervical LN = Winterbottom’s sign); occasional red, circinate patches on trunk that wax and wane; splenomegaly in chronic infection</p>	<p>Elevated IgM typical; systemic symptoms common; neurologic changes start months to years after primary infection</p>
Trypanosomiasis, American	Central and South America	Bite of infected triatomine bug; blood transfusion; ingestion of food contaminated by triatomine feces; ingestion of uncooked meat of infected animal	<p>Few days → chagoma;</p> <p>2–3 wk → systemic symptoms (days–years)</p>	Lifetime of human host	<p><i>Acute:</i> fever, LN, HSM, and HA</p> <p>Chagoma at bite site: 1–3 cm red indurated lesion (25%); Romana’s sign (periorbital chemosis) in 50% of children. <i>Chronic infection:</i> arrhythmia, CHF, megacolon, megaesophagus</p>	<p>Disease range asymptomatic to fatal; disease acute, subacute, or chronic; abnormal ECG (43%); antibody test may be helpful</p>
<b>Bacterial</b> Bartonellosis	South America: along the western slope of the Andes below 3200 m, and Guatemala	Bite of infected sandfly	3 wk to fever; 1–2 mo to eruptive stage	Weeks–years	<p>Multiple nodules, may be verrucous; fever, rigor, myalgia, arthralgias; skin lesions last 3–4 mo (range, 1 mo–2 yr); jaundice; variable HSM; generalized tender lymphadenopathy and pancytopenia; Salmonella bacteremia up to 40% coinfection</p>	<p>Fever irregular or remittent; lasts 3–4 wk; low-grade <i>Bartonella</i> bacteremia can last years; mortality 10%–50% in untreated acute disease; mortality &lt;5% in eruptive stage; skin lesion may worsen with steroid treatment; can see organism in tissue section of skin lesions</p>

Continued

Table 126-9 Differential Diagnosis of Nodular Skin Lesions—Cont'd

Cause of Nodular Lesions	Distribution	Acquisition	Incubation	Organism Survival	Common Associated Findings	Additional Information
Cat-scratch disease	Worldwide	Scratch, lick, or bite of infected cat (90%), or dog	5–7 days to primary skin lesion (range, 3–10 days); 3 wk to adenopathy (range, 3–50 days)	Months	Local lymphadenopathy; papule or pustule at inoculation site; malaise, headache, weight loss, sore throat; ESR often elevated	Risk kitten > cat; cats can have chronic asymptomatic bacteremia; rare encephalitis; angiomatous nodules in AIDS patients
Glanders	Sporadic in Asia, Africa, South America	Inhalation of aerosolized organism; direct inoculation of mucous membrane; ingestion of contaminated meat or drink	5–14 days (range, 1 day–3 wk); aerosol shorter; skin, mucous membrane longer	Weeks–years	CXR can show nodular, lobar, or peribronchial infiltration, <i>Inhalation</i> : fever, chills, myalgia, pleurisy, lymphadenopathy common; splenomegaly common. <i>Percutaneous</i> : nodular lesion; local lymphangitis may progress to ulcer, gangrene <i>Mucous membrane</i> : local inflammation <i>Disseminated</i> : papular/pustular eruption	Usually equine disease; pathogen is <i>Burkholderia mallei</i> ; can have latent infection; chronic infection → multiple subcutaneous and intramuscular abscesses with sinus tract formation; highly variable clinical presentation, from mild to rapidly fatal
Granuloma inguinale (genital) ( <i>Calyimato-bacterium granulomatis</i> )	Worldwide	Sexual contact	7–30 days (range, 3 days–6 mo)	Years in human host	Insidious onset, papule → nodule → ulcer; lesion painless; tissue response characterized by acanthosis and pseudoepitheliomatous changes	Borders of lesions well-defined and irregular; organisms visible in macrophages with Wright's or Giemsa stain (Donovan bodies)
Mycetoma Mixed bacterial and fungal infection; begins as subcutaneous nodule	Worldwide (especially in tropics)	Percutaneous inoculation	Weeks–months	Years (up to 25 yr untreated)	Granules may be discharged from wound; sinus tracts common; nodules slowly enlarge and become phlegmonous	Systemic symptoms usually absent; male: female ratio 4:1; local bone invasion in 33%; radiograph may show cortical erosion, lytic lesions; tendons spared; pathology: granuloma around purulent center Male:female ratio 6:1; rare presentation with FUI; rare distant problems (e.g., arthritis, hepatitis, pericarditis, and erythema nodosum)
Lymphogranuloma venereum (genital) ( <i>Chlamydia trachomatis</i> )	Worldwide (especially tropics and subtropics)	Direct contact (usually sexual) with infected person	7–10 days to primary lesion (range, 3–30 days); 10–30 days to inguinal bubo (range months)	Weeks–years	Painless papule → vesicle → ulcer; heals without scar; prominent, painful, fluctuant inguinal adenopathy (bubo); rectal infection → proctitis with blood, tenesmus, and mucoid discharge; fever, chills, HA, malaise, lymphadenopathy	

Rhinoscleroma ( <i>Klebsiella rhinoscleromatis</i> )	Worldwide sporadic	Uncertain	Uncertain	Months–decades	Nodular nose lesions; usually painless; slow local progression; enlarged cervical lymphadenopathy; can see destruction of bone and cartilage	Pathology: chronic histiocytic granulomatous changes Characteristic: Mikulicz's cell (large, vacuolated macrophage) Not transmitted by direct or sexual contact; infection usually acquired in childhood; untreated lesions often resolve in 1 yr, but may relapse
Syphilis, endemic; bejel ( <i>Treponema pallidum</i> subsp. <i>endemicum</i> )	Focal: Africa (Sahel), Asia (western), Australia	Exposure to contaminated utensils	Weeks (range, 2 wk–3 mo)	Months–years	Primary lesion rarely seen (<1%); secondary lesion: papillomas at corner of mouth; mucous patch on oropharynx, tongue, buccal region, later disseminated papillomas; generalized lymphadenopathy; late painful osteoperiostitis of tibia and fibula (15 %)	
Mycobacteriosis Due to <i>Mycobacterium ulcerans</i> (begins as nodule)	Focal distribution: Africa, Southeast Asia, Papua New Guinea, Australia, South and Central America	Percutaneous inoculation	6 wk (range, 3 wk–3 mo)	Years	Lesions single (98%) and extremity (90%) or trunk; nodule at onset can be pruritic; nodule → ulcer that enlarges over 1–4 mo; extensive undermined edges and necrotic base; usually no redness, LN, or systemic symptoms	Toxin-mediated process → extensive subQ necrosis BCG: limited protection Mostly found in vegetation in swampy lowlands; bony involvement < 1%
Leprosy	Worldwide (especially tropics and subtropics)	Person–person fomite	3–5 yr	Lifetime of host	Mostly subclinical; 75% with single skin lesion heal spontaneously; spectrum of disease from tuberculoid (TT) to lepromatous (LL): TT—few anesthetic asymmetrical macules/papules with red rim + hypopigmented center LL—many bilateral symmetrical lesions (macules, papules, plaques, or nodules) Iritis and keratitis common	50%–70% with no known contact of patient with leprosy; erythema nodosum seen occasionally; may worsen with pregnancy; anesthesia → trauma → deformity; ANA, RF, VDRL; may be false positive
<i>Mycobacterium marinum</i>	Worldwide	After trauma in infected water or from infected fish/crustaceans	2–3 wk	NA	Papule → larger nodule with blue/purple hue → suppuration → ulceration; sporotrichoid pattern; usually confined to superficial, cooler body tissue of extremities	Grows best at 25–32°C; pathologic findings range from pus to granulomas
Leptospirosis	Worldwide (especially tropics)	Ingestion of water or food contaminated by animal urine	7–12 days (range, 2–26 days)	Blood: 3 mo Urine: 11 mo	Pretibial, red, tender nodules 1–5 cm seen with serotype <i>Leptospira autumnalis</i>	Organism can survive weeks to months in soil and water; symptomatic infection lasts >2 wk (40%), 1 mo (7%)

Continued

Table 126-9 Differential Diagnosis of Nodular Skin Lesions—Cont'd

Cause of Nodular Lesions	Distribution	Acquisition	Incubation	Organism Survival	Common Associated Findings	Additional Information
Yaws ( <i>Treponema pallidum</i> subsp. <i>partenue</i> )	Focal warm, humid, rural areas; Africa, Asia, Central and South America, Caribbean, Oceania	Direct contact with person with infected lesion	3–5 wk (range, 10 days–3 mo)	Years–decades	Painless papule at start enlarges to 1–3 cm papillomatous raspberry-like lesion; can ulcerate → fluid teeming with spirochetes; some regional lymphadenopathy; primary lesion heals without scar in 6 mo; secondary lesions months later are disseminated papillomas in moist areas; late lesions years later cause tissue destruction and scarring	Latent infection: active disease ratio 5:1; variable presentation: self-limited to destructive chronic
<b>Fungal</b> All invasive fungal infections can cause nodular skin lesions (see Table 126-11)						
<b>Viral</b> Orf ( <i>Parapoxvirus</i> )	All goat and sheep raising countries	Close contact with infected animals with skin break	3–6 days (range, 2–7 days)	Weeks	Papule at entry site → nodule → 1–2 cm plaque/vesicle; weeping ulcer with crust develops; lesions single or multiple; usually painful; local lymphadenopathy, fever seen	Associated with exposure to sheep and goats; heals spontaneously over weeks
Pseudocowpox ( <i>Parapoxvirus</i> ) Milker's nodule	Dairy herds worldwide	Close contact with cow lesion and skin break	5–7 days (range, 5–14 days)	Weeks	Papules → 0.5–2.0 cm nodule; firm, cherry red to red/blue, painless; regional lymphadenopathy seen; no systemic symptoms	Associated with milking cows; heals spontaneously over 4–6 wk without scar
<b>Arthropod</b> Myiasis	Worldwide (especially tropics)	Many mechanisms depending on fly species; contact with infected arthropods, vegetation, food, clothes, or direct inoculation	Depends on fly: <i>Cordylobia anthropophaga</i> 7–10 days; <i>Dermatobia hominis</i> 5–12 wk	≥2 mo	Occasional eosinophilia; visible movement of maggot(s) within the lesion may be noted; larvae of some Diptera (e.g., <i>Hypoderma</i> ) migrate in soft tissues	Adult leaves host when mature

Scabies	Worldwide	Skin-to-skin contact with infected person; scabies mite acquisition from infected source (live 2 days on clothing/bedding)	Primary infection: 1 mo Repeat infection: hours/days	Months (life cycle 3–4 wk)	Severe generalized pruritus; burrows; occasional vesicles or nodules	Hypersensitivity to mite and mite products; nodules often need steroid injections to heal
Tick granuloma	Worldwide	Bite of uninfected tick	Few hours	NA	After removal of tick, a pruritic, red, papule/plaque; lasts 1–2 wk; occasionally firm nodule “tick granuloma”	At times need intralesional steroid or surgery for relief of pruritus
Tungiasis ( <i>Tunga penetrans</i> )	Tropical Central and South America, Caribbean, Africa, Asia (including India)	Skin penetration by larva of female sand flea	8–12 days	Up to 1 mo (flea dies after laying eggs)	Local pain and swelling usually on feet; tiny black spot at site of penetration	Inflammatory reaction to dead flea can persist; can result in tetanus and rarely gas gangrene

AIDS, acquired immunodeficiency syndrome; ANA, antinuclear antibody; BCG, bacille Calmette-Guérin; CHF, congestive heart failure; CNS, central nervous system; CT, computed tomography; CXR, chest x-ray film; ECG, electrocardiogram; ESR, erythrocyte sedimentation rate; FUO, fever of unknown origin; GI, gastrointestinal; HA, headache; HIV, human immunodeficiency virus; HSM, hepatosplenomegaly; LN, lymph node; NA, not available; RF, rheumatoid factor; VDRL, Venereal Disease Research Laboratories.

\*See Table 126-4.

Table 126-10 Differential Diagnosis of Ulcerative Skin Lesions

Entity	Distribution	Acquisition	Incubation	Organism Survival	Common Associated Findings	Additional Information
<b>Bacterial</b> Anthrax ( <i>Bacillus anthracis</i> )	Worldwide, sporadic; Asia, Africa, especially with animal care	Contact with infected animals or their products via skin break, inhalation, or ingestion of contaminated meat; rare biting fly transmission	2–5 days (range, 12 hr–7 days)	Duration of acute illness in human host; spores persist years in soil	Cutaneous entry (90%) → papule → vesicular with surrounding brawny, gelatinous edema; satellite lesions seen; lesion becomes hemorrhagic → necrotic → eschar; low-grade fever, malaise common	Variable disease: subclinical to rapidly fatal; toxin mediates many symptoms; 10% develop septicemic form: hemorrhagic meningitis then common, severe GI symptoms also common
Chancroid ( <i>Haemophilus ducreyi</i> )	Worldwide (especially tropics)	Sexual contact with infected person	3–10 days (range, 2–21 days)	Weeks to months	Papule/pustule ulcerates in 1–2 days (1–2 cm); edges irregular, undermined; painful ulcer; multiple ulcers (67%); unilateral/bilateral LN (40%) painful, prone to rupture	Autoinoculation can occur; 2% urethritis
Diphtheria, cutaneous ( <i>Corynebacterium diphtheriae</i> )	Worldwide	Close contact with infected person (fomite + direct contact); rarely in contaminated unpasteurized milk	2–5 days (range, 1–10 days)	Usually <2 wk; rare carriers 6 mo	Deep, punched-out ulcers covered by easily removed membrane; can look like impetigo or infected insect bite; nasopharynx infected in 20% of patients with skin infection; cardiac arrhythmias common; cranial + peripheral neuropathies seen and can persist 2–3 mo	Toxin mediates most of disease process; adults immunized as children often lack immunity (25%–75%); can superinfect other skin sores
Glanders ( <i>Burkholderia mallei</i> )	Sporadic in Asia, Africa, South America	Inhalation of aerosolized organism; direct inoculation of mucous membrane; ingestion of contaminated meat or drink	5–14 days (range, 1 day–3 wk); aerosol shorter; skin, mucous membrane longer	Weeks–years	CXR can show nodular, lobar, or peribronchial infiltration <i>Inhalation</i> : fever, chills, myalgia, pleurisy, lymphadenopathy common; splenomegaly common <i>Percutaneous</i> : nodular lesion; local lymphangitis may progress to ulcer, gangrene <i>Mucous membrane</i> : local inflammation <i>Disseminated</i> : papular/pustular eruption	Usually equine disease: can have latent infection; chronic infection → multiple subcutaneous and intramuscular abscess with sinus tract formation; highly variable clinical presentation form mild to rapidly fatal
Granuloma inguinale (genital) ( <i>Calymmatobacterium granulomatis</i> )	Worldwide	Sexual contact	7–30 days (range, 3 days–6 mo)	Years in human host	Insidious onset, papule → nodule → ulcer; lesion painless; tissue response characterized by acanthosis and pseudoepitheliomatous changes	Borders of lesions well-defined and irregular; organisms visible in macrophages with Wright's or Giemsa stain (Donovan bodies)
Leprosy	See Table 126-9				Neuropathic ulcers, especially in later tuberculoid leprosy	

Melioidosis ( <i>Bartholletia pseudomallei</i> )	Tropics and subtropics; endemic Southeast Asia	Direct contact with contaminated water or soil via skin break; aspiration of contaminated water	2 days–3 wk (range, 1 day–years)	Decades	Percutaneous entry → cellulitis, lymphangitis, bacteremia; pustular rash then due to bacteremic spread; can see chronic suppurative changes in skin, bones, CNS, liver, spleen, others; acute disease → many systemic symptoms	Pulmonary infiltrates on CXR Upper lobes 90% Cavitation 60% Disease can be acute or chronic
Mycetoma	See Table 126–9					
Mycobacteriosis Due to <i>Mycobacterium ulcerans</i> (begins as nodule)	Focal distribution: Africa, Southeast Asia, Papua New Guinea, Australia, South and Central America	Percutaneous inoculation	6 wk (range, 3 wk–3 mo)	Years	Lesions single (98%) and extremity (90%) or trunk; nodule at onset can be pruritic; nodule → ulcer that enlarges over 1–4 mo; extensive undermined edges and necrotic base; usually no redness, LN, or systemic symptoms	Toxin-mediated process → extensive subcutaneous necrosis BCG: limited protection Mostly found in vegetation in swampy lowlands; bony involvement < 1%
Plague ( <i>Yersinia pestis</i> )	Worldwide except Australia	Bite of infected flea; inhalation of airborne bacilli from a patient; bite or scratch of infected animal (e.g., cat)	2–7 days bubonic; 2–3 days pneumonic (range, 1–14 days)	No carrier state known	Abrupt onset with severe systemic symptoms; painful swollen mass/LN (bubo) seen in hours, groin > axilla; red/purple skin lesions; GI symptoms (>70%)	High mortality if untreated; septicemic form may have no bubo formation
Rickettsia* Syphilis, venereal ( <i>Treponema pallidum</i> )	Worldwide	Direct contact with infected lesion, usually sexually; transfusion of blood	2–4 wk to primary lesion	Lifetime of human host	Primary lesion: painless ulcer with indurated edge Secondary lesions: protean skin and mucous membrane lesions seen after asymptomatic interval Papule/pustule/vesicle → painful ulcer 1–6 cm diameter; circular raised edge and surrounding edema; deeply penetrating and destructive	Serologic tests do not distinguish among treponemes; disease can be acute, subacute, latent, or chronic Male > female; can see tetanus and gas gangrene; multiple and recurrent ulcers seen
Tropical ulcer (mixed bacteria including <i>Fusobacterium nucleatum</i> )	Worldwide (especially tropics)	? Minor trauma may play a role	?	Months	Inoculation papule can ulcerate	Rare form of tuberculosis
Tuberculosis, primary cutaneous	Worldwide	Unusual direct cutaneous inoculation	Months	Lifetime of human host		
Tularemia	North America, Europe, Asia (scattered)	Bite of infected arthropod or animal; contact with infected animal tissue; inhalation; ingestion of contaminated meat or water	3–5 days (range, 1–25 days)	2–4 wk in human host; organism can survive prolonged freezing	Clinical symptoms reflect portal of entry; skin inoculation → local, painful ulcer followed by painful regional lymphadenopathy, fever; rare erythema nodosum	Disease range is asymptomatic to fatal; ulceroglandular form of disease most common (75%–85%); chronic/recurrent fevers and lymphadenopathy seen (15% untreated); vaccine for high-risk persons

Continued

Table 126-10 Differential Diagnosis of Ulcerative Skin Lesions—Cont'd

Entity	Distribution	Acquisition	Incubation	Organism Survival	Common Associated Findings	Additional Information
Yaws	See Table 126-9					
Fungal	See Table 126-11				All invasive fungal infections can cause ulcerative skin lesions	Deep abscesses and sinus tracts may form
Helminthic						
Dracunculiasis	See Table 126-6				Ulcer at site of eruption of worm	
Protozoan						
Amebiasis, cutaneous	Worldwide	Infectious	1–3 wk (range, 2 days–months)	Months–years	When cutaneous, painful, rapid-growing ulcers with necrosis; genital and anal mucous membrane lesions similar to carcinoma; diarrhea/colitis	Infection more prevalent in crowded unsanitary conditions; infection more severe in infants, pregnant women, people on steroids; uncommon sexual transmission; anal > vaginal intercourse
Painful, rapidly growing ulcers; necrotic		cyst ingestion in fecally contaminated food or water			most common presentation; 1%–10% liver abscess	
Leishmaniasis, cutaneous and mucocutaneous	See Table 126-9					
Viral						
Orf ( <i>Parapoxvirus</i> )	All goat and sheep-raising countries	Close contact with infected animals with skin break	3–6 days (range, 2–7 days)	Weeks	Papule at entry site → nodule → 1–2 cm plaque/vesicle; weeping ulcer with crust develops; lesions single or multiple; usually painful; local lymphadenopathy, fever	Associated with exposure to sheep and goats; heals spontaneously over weeks
Herpes simplex	Worldwide	Type 1: direct contact with infected oral secretions Type 2: contact with genital secretions	2–12 days	Lifetime in human host	Grouped vesicles on erythematous base ulcerate; lesions painful; moderate to severe generalized systemic symptoms with primary infection; local adenopathy common	Recurrence due to latent virus in neural cells; autoinoculation possible
Arthropod						
Brown recluse spider bite ( <i>Loxosceles reclusa</i> )	?	Spider bite	Immediate–hours	NA	Bite → mild sting followed by intense pain in 2–8 hr; bullae + erythema, local ischemic necrosis, deep ulceration	Parenteral steroid use in first 24 hr controversial; heals spontaneously though scars common
Myiasis	See Table 126-8				Occasional fever, myalgias, and generalized morbilliform rash 24–48 hr after bite	Can be confused with pyoderma gangrenosum
Tungiasis	See Table 126-8					Untended ulcers, e.g., neurotropic ulcer in homeless is potential egg deposition site

BCG, bacille Calmette-Guérin; CNS, central nervous system; CXR, chest x-ray film; GI, gastrointestinal; NA, not available; LN, lymph node.

\*Several rickettsial infections are associated with an ulcerative eschar; see Table 126-2.

**Table 126-11** Differential Diagnosis of Nodular and Ulcerative Fungal Infections

Entity	Distribution	Acquisition	Incubation	Organism Survival	Common Associated Findings		
					Nodule	Ulcer	Additional Information
Primary skin infections Chromomycosis (several agents)	Worldwide, especially tropics and subtropics	Skin inoculation of nonintact skin	Weeks–months	Years	I +++	S +++	Lymphatic involvement seen, including elephantiasis and lymphedema; starts as local papule → painless, irregular, papule → nodule dissemination
Entomophthoro- mycosis ( <i>Basidiobolus</i> <i>baptisporus</i> )	Tropical Africa, rarely elsewhere	Percutaneous inoculation of nonintact skin	?	Years	Painless subcutaneous nodule → expanding woody swelling <u>Nodule</u> I +++	<u>Ulcer</u> None	Rare systemic symptoms or dissemination
Lobomycosis ( <i>Loboa loboi</i> )	Tropical Central and South America	Percutaneous inoculation of nonintact skin	1–2 yr	Years	Starts as painless, small, mobile nodules <u>Nodule</u> I +++	<u>Ulcer</u> S +	Autoinoculation seen; spontaneous regression is rare; disease only seen in humans and dolphins; histopathology characteristic
Mycetoma Mixed bacterial and fungal infection; begins as subcutaneous nodule	Worldwide (especially tropics)	Percutaneous inoculation	Weeks–months	Years (up to 25 yr untreated)	Granules may be discharged from wound; sinus tracts common; nodules slowly enlarge and become phlegmonous <u>Nodule</u> I +++	<u>Ulcer</u> S ++	Systemic symptoms usually absent; male–female ratio 4:1; local bone invasion 33%; radiograph may show cortical erosion, lytic lesions; tendons spared; pathology: granuloma around purulent center
Pityriasis (tinea) versicolor ( <i>Malassezia</i> <i>furfur</i> )	Worldwide	Direct inoculation of fungal elements	?	?	Circumscribed hypo- or hyper- (brown) pigmented scaly lesions; usually upper chest and back <u>Nodule</u> None	<u>Ulcer</u> None	Superficial stratum corneum infection; enzyme of fungus produces pigment changes
Sporotrichosis ( <i>Sporothrix</i> <i>schendkii</i> )	Worldwide	Direct percutaneous inoculation	3–8 wk	Months–years	Papule → painless; nodule → may ulcerate; secondary nodules along lymphatic channels <u>Nodule</u> I +++	<u>Ulcer</u> S +	25% extracutaneous lung, bone, joints
Tinea imbricata ( <i>Trichophyton</i> <i>concentricum</i> )	Asia: East, South, Middle; South Pacific islands; Mexico, Central and South America	Direct contact with infected person	10 days	Lifetime of host	Concentric rings 0.3–1.25 cm apart; no systemic symptoms except pruritus <u>Nodule</u> None	<u>Ulcer</u> None	Hypopigmentation more than hyperpigmentation; covers up to 70% of body

Table 126-11 Differential Diagnosis of Nodular and Ulcerative Fungal Infections—Cont'd

Entity	Distribution	Acquisition	Incubation	Organism	Common Associated Findings		
					Survival	Nodule	Ulcer
Primary nasal and oropharyngeal infections Entomophthoromycosis ( <i>Conidiobolus coronatus</i> )	Tropical Africa; rarely elsewhere	Inhalation of spore usually onto nasal turbinate	?	Years		Painless indurated mass → local insidious spread	Male-female ratio 8:1
						<u>Nodule</u> I + + + +	<u>Ulcer</u> None
Rhinosporidiosis ( <i>Rhinosporidium secheri</i> )	Worldwide (sporadic); highly endemic foci in India and Sri Lanka	Direct inoculation of fungus	Weeks–months	Years–decades		Characteristic, friable, vascular, sessile growth or polyps on mucosal surfaces; lesions painless	Treatment surgical, but recurrence common
						<u>Nodule</u> I + + + +	<u>Ulcer</u> None
Primary respiratory infections Blastomycosis ( <i>Blastomyces dermatitidis</i> )	North America (most); sporadic in Central and South America, Africa, Poland, India, Middle East	Inhalation of infectious conidia; rare percutaneous inoculation; rare STD from men with genitourinary infection	1–2 mo inhaled; 2 wk cutaneous	~15 yr in human host		<u>Nodule</u> I + + +	Mostly hematogenous to skin; 20%–80% of patients disseminated to skin, bone, genitourinary tract (male > female), CNS; soil contact increases risk; male: female ratio 3–9:1
						<u>Nodule</u> I + +	<u>Ulcer</u> S + +
Coccidioidomycosis ( <i>Coccidioides immitis</i> )	Southwest U.S., Mexico, Central and South America	Inhalation of infectious arthroconidia; rare cutaneous inoculation	2 wk	Years		Primary disease; fever, cough, chest pain, malaise Hypersensitivity reactions (15%–20%): erythema nodosum, generalized erythema, maculopapular rash, arthralgias, urticaria, rare erythema multiforme <u>Nodule</u> +	Extrapulmonary disease rare (<1 %): bone, skin, lymphadenopathy, CNS, joints, genitourinary, gastrointestinal, eye; eosinophilia common in primary infection; frequent dressing changes if open wound to prevent formation of infectious arthroconidia
						<u>Ulcer</u> +	Can cause CNS, bone, prostate, liver, eye, heart, kidney infections rarely
Cryptococcosis ( <i>Cryptococcus neoformans</i> )	Worldwide	Inhalation of infectious conidia	?	?		Mostly pulmonary; mostly asymptomatic; skin lesions 10% (hematogenous papule → nodule → ulcer) <u>Nodule</u> I + +	Can cause CNS, bone, prostate, liver, eye, heart, kidney infections rarely
						<u>Ulcer</u> S + +	

Histoplasmosis ( <i>Histoplasma capsulatum</i> )	Worldwide (but focal and sporadic)	Inhalation of infectious spores	2 wk	Years	Mostly pulmonary; mostly asymptomatic; can see skin changes (especially erythema nodosum) with hypersensitivity reaction to primary infection <u>Nodule</u> I Often oropharynx + Common skin lesions from skin and from underlying bony disease; <u>Nodule</u> I +++ Initial respiratory infection usually asymptomatic; common mucocutaneous lesions of oropharynx due to hematogenous dissemination (60%) <u>Nodule</u> I +++ <u>Ulcer</u> I +++ Ratio of disease in males and females 9:1, though skin test-positive ratio is 1:1; overall skin test only 50% sensitive; isolated CNS or adrenal involvement seen	Rare dissemination: 15%–20% metastatic skin lesions Disseminated disease can affect any organ <u>Ulcer</u> I Oropharynx + Lytic bony lesions common
Histoplasmosis, African ( <i>Histoplasma capsulatum</i> , var. <i>duboisii</i> )	Tropical Africa	Uncertain; suspect inhalation of infected spores	?	Years		
Paracoccidioidomycosis ( <i>Paracoccidioides brasiliensis</i> )	Central and South America	Inhalation of infectious spores	Months–years	Years–decades		
Penicilliosis ( <i>Penicillium marneffei</i> )	East and Southeast Asia	Inhalation/ingestion of infectious spores; rare percutaneous inoculation	9 days–1 mo	Years	Nodules actually multiple subcutaneous abscesses; ulcers from necrosis of nodules/papules <u>Nodule</u> I +++ Most patients (86%) disseminate; immunodeficiency favors ulcer formation <u>Ulcer</u> S ++	

CNS, central nervous system; I, initial lesion; S, secondary lesion; STD, sexually transmitted disease; +, scale (1–4) based on frequency when skin lesions present: +, rare; ++, uncommon; ++++, occasional; +++++, frequent.

**Table 126-12** Differential Diagnosis of a Vesicular Rash after Travel or Tropical Exposure

Organism/Agent	Disease	Comment
<b>Bacteria</b>		
<i>Bacillus anthracis</i>	Anthrax	Often associated with enlarging ulcer
<i>Brucella</i> spp.	Brucellosis	
<i>Mycobacterium tuberculosis</i>	Papulonecrotic tuberculids	Rare
<i>Mycoplasma</i> spp.	—	
<i>Rickettsia akari</i>	Rickettsialpox	
<i>Rickettsia tsutsugamushi</i> (?)	—	
<i>Streptococcus pyogenes</i> (?)	Impetigo	
<i>Vibrio vulnificus</i>		
<b>Viruses</b>		
Alphaviruses (chikungunya, O'nyong-nyong, Ross River, Sindbis)		
Enteroviruses (coxsackievirus, echovirus, enterovirus 71)		
Measles	Atypical measles	
Mumps (??)		
Monkeypox		
Herpes simplex (type 1 and type 2)		Latent virus with recurrence
Varicella-zoster	Chickenpox	Latent virus with recurrence
Vaccinia	Progressive vaccinia	Occasionally close contact of vaccine recipient
	Eczema vaccinatum	
	Accidental remote inoculation	
Variola	Smallpox	
Orf	Ecthyma contagiosum	
Tanapox		
<b>Parasitic</b>		
<i>Leishmania braziliensis</i>	American cutaneous leishmaniasis	
<i>Necator americanus</i>	Hookworm	At site of skin penetration
<b>Noninfectious</b>		
Toxic epidermal necrolysis	Drug-related	
	Vaccine-related	Rare case reports with: Bacille Calmette-Guérin Diphtheria toxoid Measles Poliomyelitis Tetanus toxoid
Plant dermatitis	Poison ivy	
Drug hypersensitivity		

nodule (pseudocowpox), tanapox, and papulonecrotic tuberculids. In addition, secondarily infected skin lesions with phage group 2 toxin-producing staphylococci can produce bullous impetigo. Noninfectious plant toxin contact, such as with poison ivy, typically results in a vesicular reaction.<sup>123</sup>

The second category consists of generalized lesions with greatest concentration on the head and scalp. Varicella (chickenpox) is the prototype of this vesicular presentation. The third group includes generalized lesions with greatest concentration on the extremities. Although predominantly peripheral, rickettsialpox lesions are noted to spare the palms and soles.<sup>21</sup> In contrast, coxsackievirus has a very characteristic predilection for those areas, resulting in the name hand-foot-and-mouth disease to describe this combination of exanthem and enanthem. Disseminated gonococcal infection is associated with painful peripheral lesions that mature into vesicles, often on a hemorrhagic base (Fig. 126-11). Toxic epidermal necrolysis and some drug hypersensitivity reactions can produce

**FIGURE 126-11** Disseminated gonococcal infection. Cutaneous lesions showing characteristic discrete pustules and papules with subcutaneous hemorrhage. (Courtesy of Kenneth J. Tomecki, MD, Cleveland, OH.)

**FIGURE 126-12** Toxic epidermal necrolysis showing large, flaccid bullae and characteristic ruptured bullae with separation of sheets of skin (Nikolsky's sign); can occur with toxin producing *S. aureus*, drug reaction, and viral illnesses. (Courtesy of Kenneth J. Tomecki, MD, Cleveland, OH.)

vesicles (Fig. 126-12). Bullae (large vesicles) are occasionally seen with gram-negative bacteria (especially *Pseudomonas aeruginosa*)-associated ecthyma lesions.<sup>7,32</sup>

### Changes in Pigmentation

Changes in skin pigmentation are usually immunologically mediated. The lesions are commonly either hypo- or hyperpigmented. In addition, they can be focal, scattered, generalized, or a combination thereof. Finally, the lesion may

be noted early or late in the disease process. Table 126-13 summarizes these findings for tropically acquired conditions associated with altered pigmentation of the skin. In general, pigmentation changes early in a disease process are more likely to result in hyperpigmentation, whereas later changes more commonly result in decreased pigmentation. This information is occasionally helpful in differentiating the underlying cause. Pinta is an example in which papulosquamous skin lesions are usually red at onset and then shift to a spectrum of blue, gray, violaceous, yellow, black, and brown, referred to as dyschromic lesions. Over many months to years, the skin lesions become depigmented macules associated with atrophic scars.<sup>124</sup>

Cutaneous jaundice is occasionally seen in patients related to hepatic involvement with various pathogens (Box 126-7). The major pathogen causing jaundice in travelers is hepatitis A. The annual incidence of hepatitis in travelers is 11 to 87 per 1000 people exposed in developing countries.<sup>1,125</sup> The agents associated with jaundice have a wide geographic distribution. The incubation period can be an important clue to the cause. Yellow fever symptoms usually begin within 2 weeks of exposure, whereas the incubation period for the hepatitis viruses is 2 to 6 weeks. Due to extensive exposure to water among triathletes and eco-challenge participants, they represent a high-risk group for water-borne illness, especially leptospirosis.

Owing to vaccine availability and excellent efficacy, the vaccination status of the traveler provides important information in formulating the differential diagnosis of the jaundiced traveler.<sup>126</sup> Rarely, both pigment alteration (e.g., erythroderma) and jaundice (e.g., immune-mediated hepatic involvement of drug hypersensitivity) can be medication related.<sup>39</sup>

**Table 126-13** Alterations in Pigmentation

	Location			Time	
	Focal	Scattered	Generalized	Early	Late
<b>Decreased pigmentation</b>					
Leishmaniasis, visceral	++ (face)	+			+(untreated)
Leprosy	+	+		+	+
Onchocerciasis	+(pretibial)				+
Pinta	+	+	+		+
Pityriasis (tinea) versicolor ( <i>Malassezia furfur</i> )		+		+	
Syphilis, venereal, secondary	++ (neck)				+
Yaws	+(inoculation site)	+(hand, wrist, feet)		+	
Yaws					
<b>Increased pigmentation</b>					
Erythrasma ( <i>Corynebacterium minutissimum</i> )	+			+	
Pinta	+	+	+	+	+
Loiasis	+			+

Leishmaniasis, visceral (especially India)			+		+

+, present; ++, common.

**Box 126-7** Diagnostic Concerns in the Traveler with Jaundice**Diseases in Which Jaundice Is Common**

Yellow fever	Symptom onset less than 2 weeks
Hepatitis A–E	Incubation to symptoms varies from 2 to 6 weeks
Rift Valley fever	Zoonotic hepatitis pathogen (arbovirus) Seen throughout Africa Transmission: mosquito, airborne, unpasteurized milk

**Diseases in Which Jaundice Is Uncommon**

Leptospirosis	Animal urine (especially rats) contaminates environment worldwide Organism can survive weeks to months in soil and water (? triathlete/eco-challenge) Incubation period 7–12 days Symptoms last 2–4 weeks Usually in setting of severe disease
Dengue fever	
Malaria	
Epstein-Barr virus	
Q fever	
Syphilis	
Drug reactions	

**TRAVEL-RELATED MEDICATIONS**

The care of patients who travel to or live in the tropics often involves the use of medications not usually prescribed by physicians in the developed world. Although medication reactions are rare, these agents represent a significant new exposure for many travelers to tropical and subtropical climates. Drug reactions can take many forms, with mechanisms both direct and immunologic. Hypersensitivity reaction types 1 to 4 have been documented with various pharmacologic agents.<sup>71</sup> The actual dermatologic presentation can take any form, from maculopapular to urticarial, vesiculobullous, or vasculitic. Other less frequent manifestations of drug eruptions include toxic epidermal necrolysis, erythema nodosum, and lichenoid reactions.<sup>127,128</sup> With few exceptions, the information related to the cutaneous reactions associated with medications in this setting comes from case reports. Table 126-14 is organized by application of the medications (e.g., antimalarials and antidiarrheals). The reactions listed for each medication appear in the approximate order of their reported incidence.

Chloroquine can occasionally induce a pruritic reaction without cutaneous changes, which can be moderately severe in up to 90% of cases. There appears to be an increased risk of a reaction to chloroquine in blacks and in people with a family history of pruritus.<sup>129</sup> If another option exists for malaria prophylaxis, it should be considered in such patients. Symptomatic patients

**Table 126-14** Cutaneous Reactions to Travel Medications

Medication	Reactions	Factors That May Increase Reactions
Antimalarials		
Chloroquine	Hair blanching  Pruritus without rash  Photosensitivity  Worsens psoriasis Rare: hypo- or hyperpigmentation of skin, blue-brown nail bed changes, erythema annulare centrifugum, bullous erythema, toxic epidermal necrolysis (TEN), erythema nodosum	Dosing $\geq 1$ yr Hair exposed to light Black race Family history of reaction Long-term usage Increased age Female > male  Pyrimethamine use Renal failure
Mefloquine	Rare: itching, varied nonspecific rashes, Stevens-Johnson syndrome	
Proguanil	Rare: mild urticaria, phototoxic reactions, exanthems, periorbital papules Hair loss Scaling of palms/soles	Female > male 2 of 6 patients receiving concurrent chloroquine
Primaquine	None reported	
Doxycycline	Photosensitivity Rare: photo-onycholysis, exanthematous pustulosis, urticaria, angioedema, purpura, anaphylaxis, serum sickness	
Quinine	Urticaria, papular rash, scarlatiniform rash, erythema multiforme Rare: fixed drug eruption; urticaria; flushing, sweating, facial edema; photosensitivity	
Halofantrine	Pruritus post-treatment	Incidence 0.3%–2.3% Black race Family member with history of pruritus post-treatment

Continued

**Table 126-14** Cutaneous Reactions to Travel Medications—Cont'd

Medication	Reactions	Factors That May Increase Reactions
<b>Antidiarrheals</b>		
Pepto-Bismol	Salicylate hypersensitivity, erythematous rash, bismuth reaction, transient darkening of tongue	
Trimethoprim–sulfamethoxazole	Diffuse maculopapular rash, allergic/toxic dermatitis Rare: erythema multiforme Exfoliative eczema exanthems Stevens-Johnson syndrome TEN	Overall incidence 2.2%; HIV/AIDS higher incidence ~1/200,000 doses ~1/200,000 doses
Ciprofloxacin	Generalized skin rash Rare: pruritus, urticaria, photosensitivity, flushing, angioedema, hyperpigmentation, erythema nodosum, fixed drug eruption, pustulosis, TEN	Incidence of 1.1%
Ofloxacin*	Generalized skin rash, pruritus, eczema Rare: hypersensitivity vasculitis, phototoxic dermatitis, photo-onycholysis	Incidence up to 14% of patients
Metronidazole	Hypersensitivity reaction, flushing, ± erythematous rash Rare: pityriasis rosea, fixed drug eruption	Alcohol ingestion
Furazolidone	Maculopapular eruptions, vesicular-morbilliform, hypersensitivity reaction, pruritic rash, contact dermatitis, erythema multiforme	0.5 % incidence rate overall (based on evaluation of 10,433 patients)
<b>Anthelmintics</b>		
Albendazole	Hair loss (reversible) Rash and pruritus Stevens-Johnson syndrome	High-dose chronic therapy
Diethylcarbamazine (DEC)	Hypersensitivity reaction (Mazzotti reaction)	Onchocerciasis >> <i>Loa</i> > other filariae
Ivermectin	Rash and pruritus	
<b>Biting arthropod repellent</b>		
Diethyltoluamide (DEET)	Rare: local irritant reaction, scarring bullous dermatitis	

\*The newer quinolones sparfloxacin and levofloxacin have photosensitivity reaction rates of 6% to 8%.  
Data from references 120–131, 133–148.

often desire treatment to relieve this bothersome reaction. Chloroquine pruritus is usually not responsive to antihistamines, although a study on chlorpheniramine showed efficacy when given 3 hours after ingestion of chloroquine in 70% of patients compared with 40% when given concomitantly.<sup>130</sup> Prednisolone 5 mg or niacin 50 mg also significantly reduced the pruritus intensity time curve in another study. Chloroquine may also exaggerate existing psoriasis; hence, psoriasis should be considered a relative contraindication to the use of chloroquine. The mechanism is possibly mediated through stimulation of a lower lymphocyte transformation. Bleaching of the hair can be seen, although usually after use longer than 1 year.<sup>131</sup>

In patients traveling to tropical and subtropical climates, there is almost always increased exposure to sunlight in both time of exposure and intensity of exposure. Sunscreens are an important part of the cutaneous hygiene in such travelers. In addition, certain medications given to travelers carry potential photosensitization as a side effect, especially doxycycline, quinine, proguanil, ciprofloxacin, and ofloxacin.<sup>71,132–135</sup> Nonsteroidal anti-inflammatory agents can also photosensitize, and sedentary travelers who are physically active during foreign travel may use them frequently.<sup>136</sup> Travelers who require these medications should be reminded to be especially vigilant about using sunscreens with high sun protection factor ratings.

For many years, diethylcarbamazine (DEC) has been the drug of choice for the treatment and occasional prophylaxis of

most filarial infections, but it can induce a significant hypersensitivity reaction in certain patients. People with onchocerciasis or loiasis are particularly at risk of developing the Mazzotti reaction.<sup>137</sup> The Mazzotti reaction is thought to be an IgE-mediated hypersensitivity reaction to dying microfilariae and is characterized by rapid onset of itching followed within hours by edema and swelling, which may progress to a generalized anaphylactoid reaction with fever, tachycardia, and hypotension. Eosinophilia, lymphadenopathy, and myalgias and arthralgias are also common. Because of the potential severity of this reaction, the first dose of DEC is often given under medical observation, especially when onchocerciasis or a high microfilarial count with *L. loa* infection are diagnosed. Administration of corticosteroids with DEC is usually effective in minimizing the inflammatory response due to the Mazzotti reaction.<sup>74</sup> Concurrent corticosteroid therapy may theoretically reduce the efficacy of DEC, although the factors influencing the ultimate clinical response to DEC are complex. In general, antihistamines have not been of great value, although broad antihistamines, such as diphenhydramine (Benadryl) and hydroxyzine (Atarax), may be more efficacious than selective H<sub>1</sub> histamine blockers.

Very rarely, travelers will develop serum sickness or serum sickness-like reactions to vaccines or antibiotics administered for travel-related disease prevention.<sup>39</sup> As a type of immune complex disease, a spectrum of reactions can be seen, from

mild morbilliform maculopapular eruptions to multisystem organ involvement arising from systemic (including cutaneous) vasculitis.<sup>128</sup> A more common presentation of serum sickness is fever, urticaria, arthralgias, and lymphadenopathy approximately 1 to 3 weeks after primary antigen exposure or 3 days after reexposure.<sup>138</sup> Rare case reports have described this reaction to bacille Calmette-Guérin, measles, and poliomyelitis vaccines, as well as to tetanus and diphtheria antitoxins.<sup>90</sup> Antibiotics such as penicillin and sulfa-containing drugs can also act as the foreign antigen initiating a cascade immune response very similar to serum sickness.<sup>139</sup> Another rare, but potentially severe, cutaneous reaction is seen with sulfadoxine pyrimethamine (Fansidar) use in malaria prophylaxis or treatment. Both Stevens-Johnson syndrome and toxic epidermal necrolysis have been reported. Development of rash during use is considered an indication to discontinue this medication.

## ACKNOWLEDGMENTS

We are indebted to Dr. Mary Wilson<sup>42</sup> for gathering an enormous amount of data related to the practical information that bears on the clinical care of patients with health concerns related to international and tropical medicine. We also acknowledge Kenneth Tomecki, MD, for his helpful review and comments. In addition, we thank Vicki Grosh for significant assistance in the preparation of the tables.

# Hepatobiliary Disease

JOHANNA P. DAILY  
JAMES H. MAGUIRE

## INTRODUCTION

The hepatobiliary tract is the target of a wide variety of tropical infections. Some diseases, such as chronic hepatitis and biliary ascariasis, are important causes of morbidity and mortality among residents of the tropics in many parts of the world. Others, such as hepatitis A, pose a greater threat to the expatriate traveler. Among the millions of persons in the tropics with the acquired immunodeficiency syndrome (AIDS), opportunistic infections with even once obscure pathogens have become important causes of hepatobiliary disease.

## DIAGNOSTIC CONSIDERATIONS

For patients with known or suspected hepatobiliary disease, categorizing the problem into one of several clinical syndromes narrows the list of diagnostic possibilities. Hence, the first step is to determine whether there is parenchymal disease of the liver (hepatitis, cirrhosis, granulomatous and other infiltrative processes, space-occupying lesions), biliary disease (biliary obstruction, other causes of jaundice), vascular disease, or splenomegaly. Priority should be given to life-threatening but treatable conditions such as hepatic abscess, cholangitis, and falciparum malaria, and to diseases that threaten the public health, such as hepatitis A and several of the viral hemorrhagic fevers. It is important to rule out diseases that are also common in temperate climates, such as cholecystitis and pancreatic carcinoma, and noninfectious processes that occur more frequently in the tropics, such as veno-occlusive disease.

The spectrum of hepatobiliary infections differs among residents of the developing world, immigrants from these areas, and the expatriate traveler.<sup>1-9</sup> Acute hepatitis A is common among travelers returning to temperate zones, who typically lack prior exposure and immunity, while it is rare among immigrants and adult residents of the tropics, who experienced infection during childhood.<sup>10</sup> Biliary ascariasis is familiar to clinicians in the developing world, where a large proportion of the population harbors adult worms (see Chapter 109).<sup>11-14</sup> Although ascariasis is not uncommon among immigrants from the tropics, the risk of hepatobiliary complications decreases rapidly during the first year after arrival, because the worms die and are not replaced.

Routine evaluation of the patient begins with a clinical history that may help distinguish between disease processes and point to a diagnosis. There should be questions about the pace of illness, right upper quadrant pain or discomfort, indigestion, jaundice, dark urine, pruritus, fever, anorexia, and other constitutional symptoms. A history of underlying conditions, medications, vaccinations, and an epidemiological history of exposures should be taken. Examination should evaluate the size, consistency, and tenderness of the liver, spleen, and gallbladder. The presence of jaundice, ascites, dilated periumbilical veins, spider angiomas, or other stigmata of liver disease should be ascertained. Measurements of serum bilirubin, liver enzymes, and alkaline phosphatase are part of routine screening for hepatobiliary disease. Depending on their availability, further studies such as measurements of serum albumin and prothrombin time, serologic tests, imaging studies, cholangiography, and liver biopsy may be indicated.

Ultrasonography (US) is more widely available in tropical areas than computed tomography (CT) or magnetic resonance imaging (MRI). US is useful for detecting gallstones, dilated biliary ducts, thickened gallbladder walls, masses within and around the liver, periportal fibrosis, hepatosplenomegaly, and evidence of portal hypertension. US can distinguish solid lesions from abscesses and cysts and can demonstrate certain helminths within the hepatobiliary tree.<sup>15-17</sup>

In the sections to follow, diseases of the hepatobiliary tree are discussed according to clinical syndromes and manifestations. Emphasis is on differential diagnosis and the approach to diagnosis.

## ACUTE HEPATITIS

The clinical spectrum of acute hepatitis ranges from asymptomatic illness to fulminant, massive hepatic necrosis. In typical symptomatic cases, there is vague discomfort and tenderness in the right upper quadrant, nausea, anorexia, jaundice, and fever. The broad differential diagnosis is outlined in Figure 127-1. In all cases, a history of exposure to toxins and drugs that cause damage to the liver should be sought.

Elevation of hepatic enzymes and bilirubin also occurs in response to a number of systemic infections, including bacterial sepsis, pneumonia, typhoid fever, and malaria, even when the pathogen does not directly infect liver tissue.<sup>1,18</sup> Cholestasis and frank jaundice are prominent in such cases and may take days to several weeks to resolve after the responsible infection is cleared. In malaria, hepatomegaly without evidence of hepatocellular injury can occur as a consequence of vascular congestion and Kupffer cell hyperplasia.

The most common causes of hepatitis throughout the world are hepatitis viruses A through E (see Chapter 64). In many developing regions, hepatitis A virus (HAV) infection occurs in the first years of life through fecal-oral transmission and is usually asymptomatic.<sup>19</sup> In areas where the quality of drinking water has improved, however, the prevalence of hepatitis A in children has decreased in recent years.<sup>20</sup> Hepatitis A infection is one of the most common causes of illness among travelers to the tropics, occurring at a rate of 3 to 6 per 1000 persons per month in one study and accounting for 60% of cases of hepatitis in returning travelers.<sup>21</sup> Appropriate use of hepatitis A vaccine or pooled serum immunoglobulin reduces the risk of infection among travelers to less than 5% and 15%, respectively.<sup>22</sup>

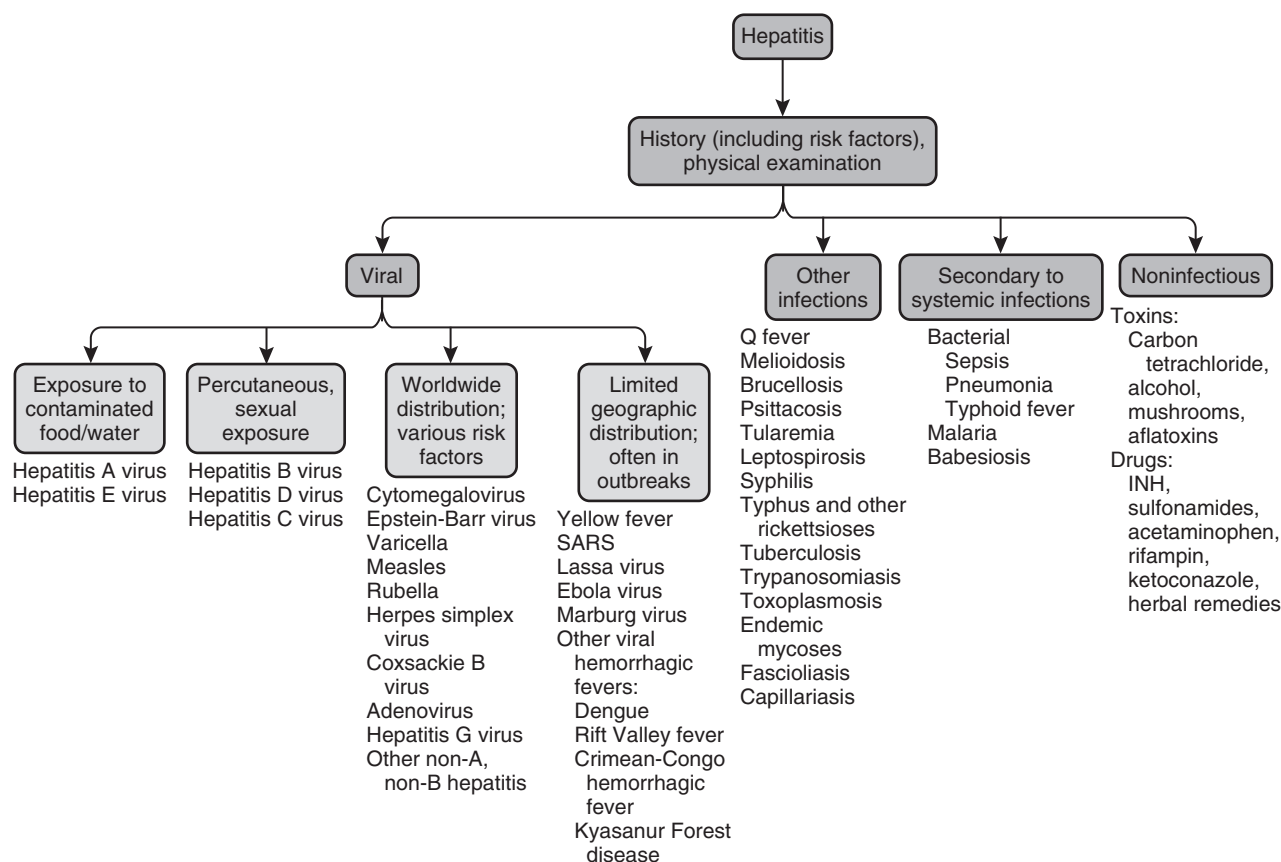

FIGURE 127-1 Differential diagnosis of acute hepatitis.

The prevalence of hepatitis B surface antigenemia varies from less than 1% in Mexico and temperate South America to as high as 15% in parts of Africa, Southeast Asia, China, the Philippines, Pacific islands, Middle East, and the Amazon basin.<sup>23,24</sup> Residents of such areas generally acquire asymptomatic infections in the perinatal and early childhood periods. Acute hepatitis B is four to five times less common than hepatitis A among travelers to the tropics.<sup>25</sup> Expatriates at high risk for hepatitis B include health-care professionals, persons receiving inoculations or dental treatment, and those who engage in unprotected sexual contact or share needles.<sup>26</sup> Only persons infected with hepatitis B virus (HBV) are at risk for superinfection with delta virus (hepatitis D virus, HDV). Direct person-to-person contact of HDV has been responsible for the high number of cases of fulminant hepatitis in the Amazon region (Lábrea hepatitis), northern Colombia (hepatitis of the Sierra Nevada of Santa Marta), and remote Amerindian settlements in Venezuela, rather than percutaneous needle exposure, which is the usual route in other parts of the world.<sup>27–29</sup>

Acute hepatitis C virus (HCV) infection occurs usually via the parenteral route, or less commonly via sexual transmission. It is endemic worldwide with high prevalence in Japan and the Mediterranean countries of Europe, Africa, and the Middle East, where it causes significant morbidity, but is rare among returning travelers.<sup>30–32</sup> High rates of hepatitis C infection in Egypt are attributed to use of inadequately sterilized needles for administration of tartar emetic during mass

treatment campaigns to control schistosomiasis in the 1960s through the 1980s.<sup>33</sup> Another virus transmitted via the fecal-oral route, hepatitis E, has caused outbreaks in India, Nepal, Pakistan, the former Soviet Union; parts of Africa, Mexico, and China; and the Middle East. Sporadic cases have been reported among travelers.<sup>34–36</sup>

Distinguishing the different types of hepatitis on clinical grounds alone is difficult. The incubation periods of hepatitis A and B are 2 to 6 weeks and 6 weeks to 6 months, respectively. The hepatic manifestations of HBV infection may be preceded by rash, arthralgia, and arthritis. Mortality due to fulminant hepatitis occurs in 0.15% of persons with HAV infection (and in 2% to 3% of those over the age of 40 years), in fewer than 1% of those with HBV infection, in up to 50% of those with HDV co-infection, and in up to 20% of pregnant women during the third trimester who become infected with hepatitis E virus (HEV).

There are specific immunoglobulin M (IgM) antibody tests for hepatitis A, D, and E. Acute hepatitis B is diagnosed using assays for hepatitis B surface antigen or anti-HBV core antigen.<sup>37,38</sup> Diagnosis of acute hepatitis C requires detection of HCV RNA, since anti-HCV antibodies are usually slow to develop. Household contacts of patients with hepatitis A should receive serum immunoglobulin, and precautions to prevent enteric spread should be taken. Hepatitis B immune globulin and immunization are effective in preventing infection of sexual partners and neonates born to infected mothers.

Other viruses that cause acute hepatitis are listed in Figure 127-1.<sup>39</sup> Diagnosis is made by serologic tests, microscopic examination of biopsy specimens, and viral cultures of liver tissue, blood, urine, and other fluids. In the forested areas of sub-Saharan Africa and South America, yellow fever occurs in epidemics or as sporadic cases among unvaccinated persons, including the occasional traveler (see Chapter 71). Only 10% to 20% of cases of infection with the yellow fever virus lead to the classic syndrome of biphasic fever, jaundice, hemorrhage, and hepatic necrosis. Other agents of viral hemorrhagic fever that involve the liver include the tick-borne Kyasanur Forest disease in India and Crimean-Congo hemorrhagic fever in Africa and Asia; Lassa fever in West Africa; Marburg virus disease in Uganda, Kenya, and Zimbabwe; and Ebola virus disease in Zaire and Sudan (see Chapters 65–67, and 70).<sup>40</sup> Because transmission of the highly lethal Lassa fever, Marburg, and Ebola viruses is by direct contact with blood and excreta, strict isolation and infection control precautions are indicated. Hepatic necrosis has been reported also with dengue hemorrhagic fever and Rift Valley fever. Hepatic impairment and elevated levels of transaminases in the serum that occur in up to 60% of persons with the severe acute respiratory syndrome (SARS) are due to infection of the liver with the SARS-associated coronavirus.<sup>41</sup>

Hepatomegaly and, at times, clinically apparent hepatitis are seen in nonviral infections such as leptospirosis, relapsing fever, and early syphilis (see Chapters 44–46). Hepatitis is rare in Lyme borreliosis. In leptospirosis, the elevation of serum bilirubin is usually out of proportion to that of the hepatic enzymes. Leptospirosis is enzootic throughout the tropics, and outbreaks among residents and travelers in the tropics have followed contact with contaminated water or moist soil.<sup>42,43</sup>

Pulmonary involvement and a history of contact with livestock or parturient cats clinically distinguishes the hepatitis of acute Q fever from that of viral hepatitis. Hepatomegaly or hepatitis occurs frequently in typhoid fever, acute brucellosis, tularemia, meloidosis, and psittacosis, as well as in rickettsioses.<sup>44,45</sup> Massive hepatic necrosis may complicate miliary tuberculosis.<sup>46</sup>

A mild increase in serum transaminases can be seen in cases of acute acquired toxoplasmosis. Mild hepatomegaly during acute Chagas' disease results from infection of hepatocytes and Kupffer cells and the host's immune response (see Chapter 93). Approximately 2 months after ingestion of watercress containing metacercariae of *Fasciola hepatica*, immature flukes migrate through the liver, causing right upper quadrant pain, nausea, and fever (see Chapter 117). Tender hepatomegaly and elevated serum hepatic enzymes are suggestive of viral hepatitis, but a marked peripheral blood eosinophilia and urticarial eruptions point to the proper diagnosis. Hypoechoic and hypodense lesions of the liver detected by US and CT correspond to the track of the parasite as it burrows through the liver.<sup>16,47</sup> Diagnosis of acute fascioliasis is made by serologic tests because symptoms precede egg-laying by weeks.<sup>48</sup> Rare human cases of *Capillaria hepatica* have been reported from Africa, Asia, and Latin America (see Chapter 106).<sup>49</sup> Acutely, there may be tender hepatomegaly and anorexia. The diagnosis is suggested by peripheral blood eosinophilia and confirmed by demonstration of worms and eggs in the liver by biopsy or at autopsy.

Hepatomegaly in acute schistosomiasis results from egg deposition in the liver and the immune response to worm and egg antigens (see Chapter 116).<sup>50</sup> Specific serologic tests become positive several weeks before eggs can be found in the stool.

## CHRONIC HEPATITIS AND OTHER CAUSES OF DIFFUSE HEPATOMEGALY

Chronic active hepatitis in the tropics is caused most commonly by HBV and HCV (see Chapter 64). Co-infection with HDV may accelerate the course of chronic HBV infection. While failure to resolve infection with these agents may lead to cirrhosis or hepatoma, persons with chronic hepatitis may remain asymptomatic for years, despite persistently elevated hepatic enzymes. Serologic testing and liver biopsy confirm the diagnosis.

Macronodular or "postnecrotic" cirrhosis develops in up to 25% of chronic hepatitis B surface antigen carriers and in over 20% of persons infected with HCV for over 20 years. The process may be clinically silent for several years before the appearance of symptoms and signs of hepatocellular dysfunction and portal hypertension such as jaundice, encephalopathy, ascites, and bleeding from esophageal varices. The liver is firm, nodular, and shrunken.

The periportal or "pipe stem" fibrosis of chronic schistosomiasis gives the liver a nodular appearance which resembles that of cirrhosis. True cirrhosis in schistosomiasis, however, is usually due to coinfection with HBV or HCV, or other chronic liver disease, and only occasionally is it seen in the absence of other hepatic lesions.<sup>51</sup> Cirrhosis has been reported as a consequence of visceral leishmaniasis.

Chronic alcoholism is a common cause of micronodular cirrhosis in the tropics. African or Bantu cirrhosis is thought to be related in part to chronic iron overload and hemochromatosis, whereas Indian childhood cirrhosis may be related to high copper intake as well as genetic factors.<sup>52</sup> Many cases of cirrhosis in the tropics remain undiagnosed. The differential diagnosis of hepatomegaly is shown in Box 127-1.

## Granulomatous Disease

Systemic infections may infiltrate the liver and induce granuloma formation. Usually, both the liver and spleen are enlarged, and the alkaline phosphatase is elevated. In visceral leishmaniasis, disseminated tuberculosis, atypical mycobacterial infections, histoplasmosis, disseminated *Penicillium marneffei* infection, and other fungal infections, organisms invade Kupffer cells and other cells of the reticuloendothelial system. Disseminated infections of this sort are common in advanced human immunodeficiency virus (HIV) disease, but because of impaired immunity there may be little or no granulomatous reaction on histologic examination. Diagnosis is made by microscopic examination of biopsied liver tissue and culture of tissue and blood.

In chronic schistosomiasis *mansoni* and schistosomiasis *japonica*, granulomas form around eggs trapped in portal venules. Typically, the left lobe of the liver is enlarged more than the right lobe. As infection progresses, the size of the liver decreases as the diameter of the granulomas is reduced by immunomodulation. Periportal fibrosis, a specific finding in hepatosplenic schistosomiasis, is detected by US, CT, and MRI. In *Schistosoma japonicum* infection, calcified eggs in the liver

produce a characteristic “turtle-back” pattern on MRI. In severe cases, portal hypertension may lead to gastroesophageal varices, but jaundice, ascites, and hepatic encephalopathy are only seen in “decompensated” cases in which there is hepatocellular damage as well as portal hypertension. The diagnosis of chronic schistosomiasis is made by finding eggs in specimens of stool. Serologic tests are useful for screening travelers, who often have light and asymptomatic infections. Hepatosplenomegaly and early periportal fibrosis may regress after treatment with praziquantel.

Granulomas may form around migrating filariform larvae of *Strongyloides* during hyperinfection and dissemination. Granulomas form around *Ascaris* eggs trapped in liver tissue when adult worms enter the biliary tree. Hepatic granulomas around adult worms, larvae, and eggs are characteristic of chronic *Capillaria hepatica* infection. In visceral larva migrans due to *Toxocara canis* or *Baylisascaris procyonis*, migrating larvae provoke an eosinophilic granulomatous response.<sup>53</sup> Hepatomegaly, fever, and peripheral blood eosinophilia prompt a clinical diagnosis, which can be confirmed by serologic tests.

**Space-Occupying Lesions of the Liver**

Symptoms of mass lesions in the liver produce abdominal discomfort from distention of Glisson’s capsule, an increase in abdominal girth, obstruction of the biliary system, or rupture into the peritoneum, pericardium, or pleural space or through the abdominal wall. Asymptomatic lesions occasionally are detected by imaging procedures during evaluation of unexplained fever or weight loss. The characteristics of lesions imaged by US, CT, or MRI may yield a precise diagnosis of certain helminthic infections such as schistosomiasis, acute fascioliasis, or echinococcosis, but the cause of most lesions is determined by serologic tests, blood cultures, or culture and microscopic examination of specimens obtained by aspiration or biopsy.

Liver abscesses, whether amebic or bacterial, may present subacutely with low-grade fever, weight loss, and localized pain, or acutely with temperatures above 102°F and signs of toxicity. Jaundice is unusual in the absence of biliary obstruction, and the alkaline phosphatase may be the only hepatic enzyme that is elevated.

Certain features may help differentiate amebic and bacterial abscesses<sup>54</sup> (Fig. 127-2). Amebic abscesses occur frequently in Mexico, Central America, northern South America, West and South Africa, and India. Most persons with amebic abscesses do not have dysentery, and stool examination does not show trophozoites or cysts in 50% of those tested. Serologic tests for antiamebic antibodies become positive in 99% of persons after 7 days of symptoms. Antibodies may persist for years, however, and the specificity of serologic tests may be low in endemic areas. Aspiration of the abscess usually is not necessary for diagnosis; abscess fluid typically contains few or no amebae, rare white blood cells, and no bacteria. A trial of metronidazole or tinidazole confirms a clinical diagnosis if patients defervesce or show symptomatic improvement within a few days.<sup>55</sup> Aspiration is indicated in cases of pending rupture or in cases with uncertain diagnoses that do not respond to medical treatment.<sup>56</sup> Treatment with metronidazole or tinidazole should be followed by a course of a luminal amebicide such as paromomycin, iodoquinol, or diloxanide furoate.

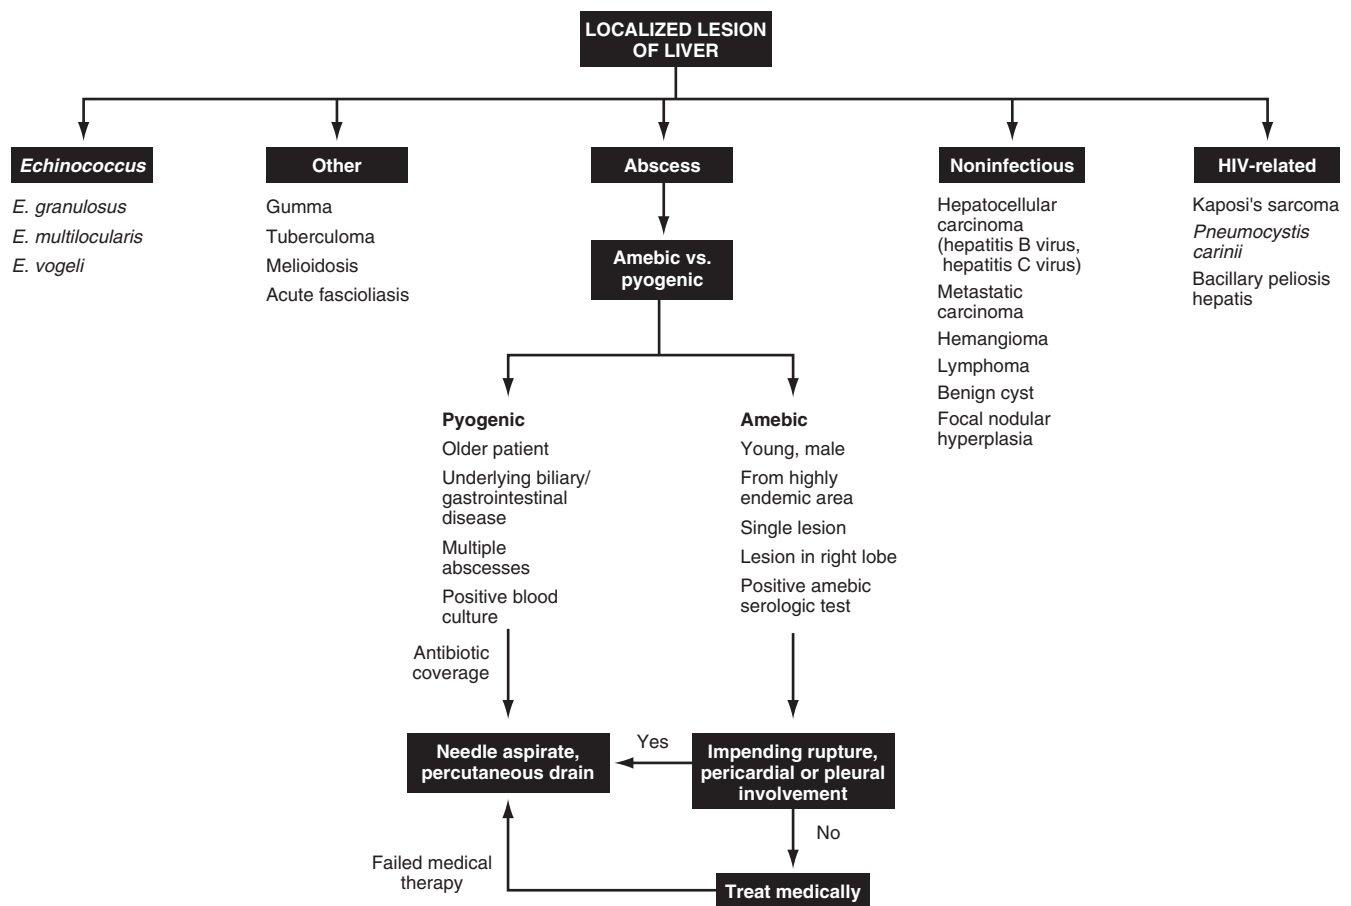

FIGURE 127-2 Differential diagnosis of space-occupying lesions of the liver.

Pyogenic liver abscesses most commonly are caused by enteric organisms, streptococci, and *Staphylococcus aureus*.<sup>57</sup> Blood cultures and cultures of abscess fluid are positive in about 50% and 73% of persons, respectively.<sup>58</sup> In the tropics, *Salmonella typhi*, *Brucella* species, and *Burkholderia* (*Pseudomonas*) *pseudomallei* occasionally cause hepatic abscesses. Occasional causes of large space-occupying lesions in the liver include tuberculosis, gummatous syphilis, and, in persons with AIDS, bartonellosis (peliosis hepatis), and *Pneumocystis jirovecii*. During acute fascioliasis, CT or MR often show hypodense lesions in the liver measuring 1 cm or more in diameter that move to different parts of the liver over the course of several weeks. These lesions correspond to the tortuous and branching linear tracks of necrotic tissue and eosinophilic inflammatory infiltrates along the path of larval migration.<sup>59</sup>

Hydatid cysts of the liver (see Chapter 114) may be distinguished from simple hepatic cysts when US, CT, or MRI shows intracystic septations indicative of daughter cysts. Otherwise, a history of residence in a sheep raising or other endemic area or a history of urticarial or anaphylactic reactions may suggest the diagnosis of hydatid disease. A highly sensitive enzyme-linked immunosorbent assay (ELISA) and confirmatory immunoblot for antibodies to *Echinococcus granulosus* are available.<sup>60</sup> Microscopic examination of cyst fluid taken by needle aspiration or at surgery usually shows diagnostic protoscolices, hooklets, and calcareous bodies.<sup>61</sup>

Treatment includes high-dose albendazole and either careful surgery or percutaneous drainage with inactivation of cysts.<sup>62,63</sup> Less common cestodes that cause mass lesions in the liver include *Echinococcus multilocularis* in northern regions of the world and *Echinococcus vogeli* and *Echinococcus oligarthrus* in Central and South America.<sup>64</sup> Hepatic cysticercosis is unusual.

### Vascular Disease

Chronic passive congestion of the liver due to heart failure may produce chronic hepatomegaly and eventually cardiac cirrhosis. In tropical areas, important causes include chronic Chagas' cardiomyopathy, rheumatic heart disease, restrictive pericarditis from tuberculosis, and endomyocardial fibrosis. Veno-occlusive disease involving hepatic venules causes rapidly progressive tender hepatomegaly, ascites, and death from variceal bleeding or liver failure. It is associated with ingestion of pyrrolizidine alkaloids in herbal teas in Jamaica and parts of Africa and Asia.<sup>65</sup>

### Splenomegaly

The spleen is enlarged in many of the same infections in which the liver is enlarged (Box 127-2). Massive splenomegaly may be seen in visceral leishmaniasis, chronic

\*Many of the infectious diseases listed in Box 127-1 can also cause splenomegaly.

malaria (tropical splenomegaly syndrome), and myeloproliferative disorders.<sup>66</sup> Splenomegaly secondary to portal hypertension occurs with schistosomiasis, cirrhosis, and many other severe chronic liver diseases. Unusual causes of splenomegaly in the tropics include abscesses due to *Salmonella typhi*, *Brucella* species (especially *B. suis*), and *Burkholderia* (*Pseudomonas*) *pseudomallei*. Hypoechoic lesions in the spleen have been detected by ultrasonography in persons with loiasis.<sup>67</sup>

**JAUNDICE**

Tropical infectious diseases produce jaundice by several mechanisms (Fig. 127-3). Hemolysis leading to predominantly unconjugated hyperbilirubinemia and depressed serum haptoglobin levels is the result of direct infection of red blood cells by *Plasmodia*, *Babesia*, and *Bartonella bacilliformis*. It also may

occur via indirect mechanisms such as disseminated intravascular coagulation accompanying a variety of systemic infections or the hemolytic-uremic syndrome associated with *Escherichia coli* O157-H7. Mixed conjugated and unconjugated hyperbilirubinemia is seen with infections that produce hepatitis by directly or indirectly damaging hepatocytes, as discussed earlier. Typically, there is an element of intrahepatic cholestasis in addition to impaired uptake and conjugation of bilirubin.

Obstruction of biliary ducts by stones, tumors, strictures, and certain infections produces marked elevation of the serum conjugated bilirubin and serum alkaline phosphatase, 5-nucleotidase, and  $\gamma$ -glutamyltranspeptidase. US, CT, and endoscopic cholangiography assist in the identification of the cause of obstruction.

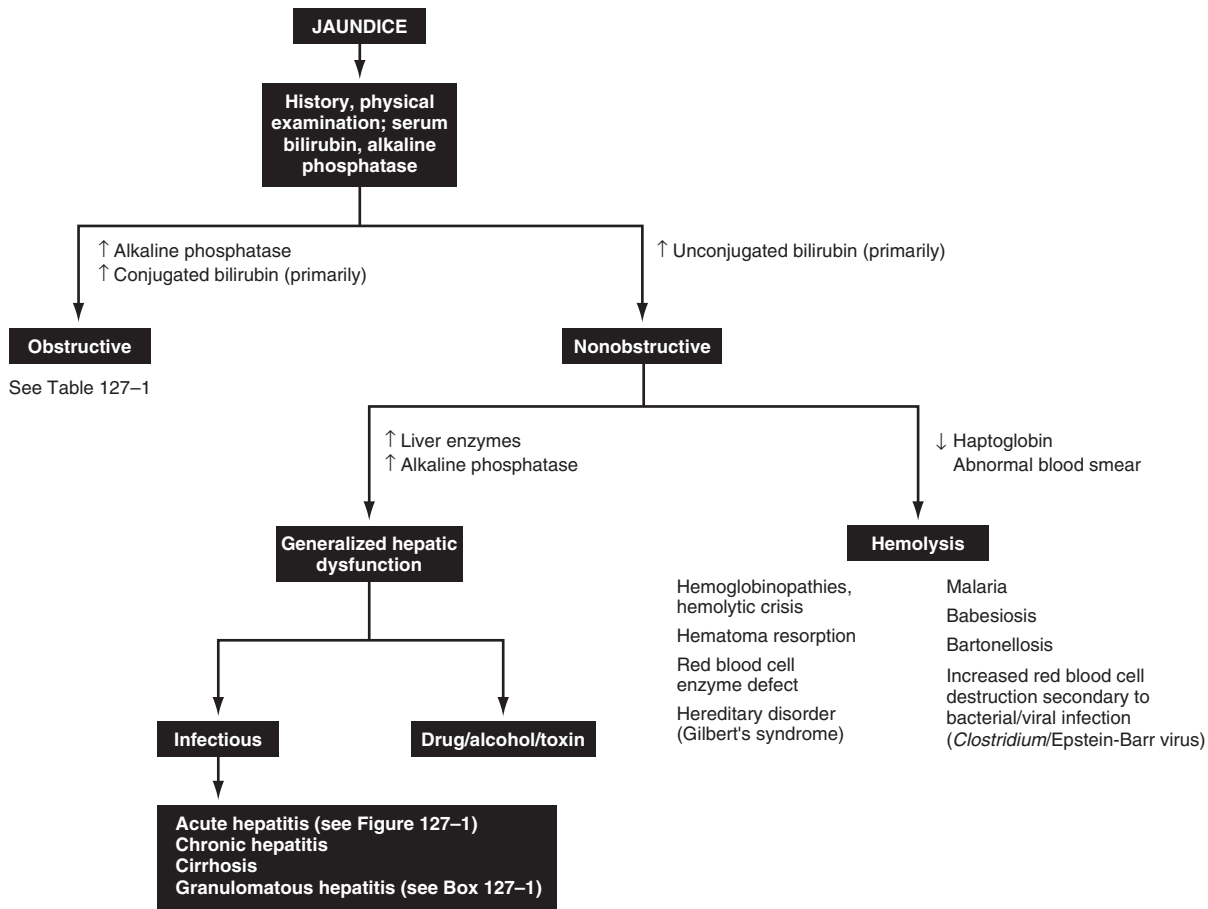

**BILIARY OBSTRUCTION**

Obstruction of the biliary or cystic duct leads to biliary colic with right upper quadrant pain or pressure of sudden onset that radiates to the shoulder (Table 127-1). Persistence and progression of the pain, frequently with nausea, vomiting, localized peritoneal signs, and low-grade fever suggest cholecystitis. High fevers, shaking chills, leukocytosis, and jaundice suggest cholangitis, which may lead to septicemia and shock. Gradual obstruction of the common bile duct leads to painless jaundice, often with pruritus.

Obstruction of the biliary tract in the tropics is frequently caused by parasitic infections. Biliary ascariasis (see Chapter 109)

**Table 127-1** Causes of Obstructive Biliary Disease in the Tropics

Infectious	Noninfectious
Leptospirosis	Neoplasma

complicates chronic ascariasis in fewer than 0.1% of cases, but the huge number of infected persons makes the condition an important cause of hepatobiliary disease.<sup>11</sup> When individual adult worms enter and exit the bile ducts, symptoms of biliary colic are intermittent, but when worms fail to exit the duct, pyogenic cholangitis, hemorrhagic pancreatitis, or liver abscesses may result. Worms that die in the biliary tree may form the nidus of gallstones.<sup>68</sup> In a series of 500 patients with biliary and pancreatic ascariasis in India, 56% had biliary colic, 24% had acute cholangitis, 13% had acute cholecystitis, 6% had pancreatitis, and 1% had liver abscesses.<sup>14</sup> The diagnosis is made by US, CT, cholangiography, or endoscopic retrograde cholangiopancreatography (ERCP) and may demonstrate worms in the biliary or pancreatic ducts or gallbladder.<sup>69,70</sup> Treatment consists of extraction of worms during ERCP or anthelmintic treatment, preferably with pyrantel pamoate, which acts rapidly and paralyzes the worms. Nasogastric suction, antispasmodics, analgesics, and intravenous fluids usually obviate the need for surgery.

Clonorchiasis and opisthorchiasis (see Chapter 117) are common infections in Southeast Asia, China, and other parts of Asia where carp is consumed without proper cooking.<sup>71,72</sup> Most persons are asymptomatic, but small numbers of persons with long-standing infection develop recurrent episodes of cholangitis or cholangiocarcinoma.<sup>73</sup> Adult flukes that inhabit the bile ducts and gallbladder are responsible for hyperplasia

of the ductal epithelium and occasionally biliary stones or pancreatitis. Chronic infections with adult *Fasciola hepatica* and *Fasciola gigantica* may remain asymptomatic for years before adult worms cause cholecystitis and cholangitis.<sup>74</sup> Hemobilia from ulceration of biliary epithelium, sclerosing cholangitis, and biliary stones are unusual complications of chronic fascioliasis.<sup>75</sup> The diagnosis of chronic clonorchiasis, opisthorchiasis, and fascioliasis is made by identifying eggs in the stool or bile or identifying adult worms by cholangiography or visually at the time of surgery. US and CT may demonstrate adult *Fasciola*. *Paragonimus* has been reported to cause obstructive granulomas involving the biliary tree resulting in biliary cirrhosis (see Chapter 117).<sup>76</sup>

Hydatid cysts of the liver (see Chapter 114) cause biliary obstruction by compressing biliary radicals as they grow or by rupturing into the biliary tree and causing blockage with daughter cysts and cyst membranes.<sup>77</sup> Cyst rupture can be provoked by trauma and may lead to bacterial cholangitis, liver abscess, and anaphylactic reactions to the highly antigenic cyst contents.

Other parasitic causes of biliary diseases include *Cryptosporidium parvum* (see Chapter 88) and microsporidia (see Chapter 96) in persons with AIDS. Findings are similar to those of primary sclerosing cholangitis, with diffuse involvement of intrahepatic or extrahepatic bile ducts, or both, strictures, ampullary stenosis, and pancreatic duct involvement.

ERCP defines the lesions anatomically, and examination of feces or bile for oocysts of cryptosporidia or *Isospora* or spores of microsporidia are diagnostic. AIDS-associated cholangiopathy may also be caused by cytomegalovirus, *Mycobacterium avium* complex, *Mycobacterium tuberculosis*, and *Histoplasma capsulatum*.<sup>78-81</sup>

Acalculous cholecystitis may be provoked by organisms that infect the gallbladder in the absence of stones. Leptospirosis, salmonellosis, and giardiasis have been implicated in immunocompetent persons, and the same agents that cause AIDS-associated cholangiopathy occasionally cause acalculous cholecystitis in HIV-infected persons. Acalculous cholecystitis has been seen in association with systemic infections such as actinomycosis, tuberculosis, and syphilis.

Cholelithiasis has become more common in some developing areas as residents have adopted a westernized diet.<sup>1</sup> In addition, gallstones result from chronic hemolytic states such as sickle cell anemia and other hemoglobinopathies and malaria. Recurrent pyogenic cholangitis is a condition of unknown cause in the Far East in which there is formation of pigment stones and sludge. It has been suggested that parasites such as *Clonorchis*, *Opisthorchis*, and *Ascaris* act as the nidus for stone formation in this condition, but dietary deficiencies that alter bile salt metabolism may be more important.

## HIV INFECTION AND HEPATOBIILIARY DISEASE

HIV infection, which is highly prevalent in many parts of the tropics (see Chapters 76 and 133), may alter the natural history, clinical presentation, diagnosis, and management of infections involving the liver and biliary tract. For example, HIV infection may lead to unusual clinical syndromes, such as cholangitis caused by cytomegalovirus, intestinal coccidia, microsporidia, and mycobacteria, or bacterial peliosis due to *Bartonella*. HIV co-infection has been associated with decreased egg excretion in persons with *S. mansoni* due to impaired granuloma formation and increased trapping of eggs in tissue. Serologic tests for the diagnosis of visceral leishmaniasis may yield false negative results in HIV-infected patients, but recovery of parasites from the peripheral blood is enhanced. Treatment of certain infections of the hepatobiliary tract in persons infected with HIV may present difficult challenges, such as the high rate of relapse of visceral leishmaniasis following standard therapy. Importantly, highly active antiretroviral therapy (HAART) may play a key role in preventing progression of latent diseases, reducing the rate of relapse, and enhancing efficacy of treatment.<sup>82,83</sup>

# Approach to the Patient in the Tropics with Pulmonary Disease

GREGORY J. MARTIN

Pulmonary disease is one of the leading causes of morbidity and mortality throughout the world and respiratory tract infections are the most frequent infections of humans.<sup>1</sup> As represented in Box 128-1, four of the ten leading causes of global death reported to the World Health Organization (WHO) are attributable to some form of acute or chronic pulmonary disease.<sup>2</sup> The viral, bacterial, fungal, and protozoal etiologies of worldwide lung disease are protean. Tropical pulmonary disease includes most temperate climate etiologies as well as a greater incidence and prevalence of tuberculosis (TB), human immunodeficiency virus (HIV)-related disease, and helminthic infections. Diverse factors such as poverty, crowding, malnutrition, and proximity to animals are responsible for a range of diseases that are infrequently encountered outside the tropics.

As developing nations make economic transitions, smoking and unregulated occupational and environmental exposures become significant risk factors for previously uncommon pneumoconioses and respiratory malignancies.<sup>3,4</sup> Conversely, as travel between industrialized and tropical nations increases, agents responsible for localized outbreaks of disease in remote,

undeveloped areas have been more frequently imported to the industrialized world. Most notably, in China and Southeast Asia in 2003, the ability of a zoonotic coronavirus (later designated SARS CoV) to infect humans led to the severe acute respiratory syndrome (SARS). SARS quickly became a major public health emergency not only in much of Asia but also in Canada and, to a lesser extent, in the United States and Europe. Novel influenza viruses have commonly been first discovered in tropical Asian populations where animals, especially chickens, ducks, and pigs, are often kept in close proximity to humans. As outbreaks of avian (and swine) influenza occur in these areas, sporadic cases of these same strains occur in humans, creating the potential for human-zoonotic recombinations and the possibility of returning travelers presenting with these "exotic" strains.

The following overview is designed as a starting point in developing a differential diagnosis for patients presenting with pulmonary complaints who have had exposure in the tropics. Emphasis will be given to those entities found exclusively or more commonly in the tropics. In Table 128-1, parasitic etiologies associated with respiratory disease from the tropics and their geographic distributions are shown and demonstrates the diversity of pathogens that must be considered.<sup>5</sup> The specific disease entities and treatment are fully described in the individual pathogen chapters of the text.

Clinicians evaluate patients' illnesses in geographic areas differently depending on the resources available and the local prevalence of diseases. In developing a differential diagnosis for respiratory complaints, it is helpful to consider patients in three relatively distinct groups that have considerable differences in their exposure to various risk factors:

1. Lifelong denizens of the tropics (as well as those from the tropics who have recently immigrated to a temperate area)
2. Travelers who have returned from the tropics after short (less than 1 month) visits
3. Expatriates from temperate areas who are currently living in or have just returned from the tropics.

Even when coming from (or living in) the same region, the etiologies and diagnostic approaches to each of these groups may be quite different as the intensity of their exposures, potential contact with infected individuals, and access to medical care (and advanced diagnostics) may be significantly diverse. For example, a patient who presents with hemoptysis in most industrialized nations has a high likelihood of having a lung neoplasm, whereas natives of the tropics with hemoptysis are much more likely to have tuberculosis, and the differential diagnosis for an expatriate living in the tropics falls somewhere between these two groups.<sup>6</sup>

## ACUTE RESPIRATORY TRACT INFECTIONS, INCLUDING PNEUMONIA

Acute respiratory tract infections (ARIs) include a spectrum of illnesses from colds and influenza to streptococcal pharyngitis and pneumococcal pneumonia. As such, they may be little more than an annoyance or they may be associated with a fulminant course and significant morbidity and mortality.

Upper respiratory illnesses (URIs) are the most common infections in humans in both temperate and tropical climates and are primarily viral in etiology. The frequency of respiratory

infections among children is much greater than in adults.<sup>7</sup> Although the frequency of URIs in the tropics appears to be no higher than in temperate climates, children in the tropics often suffer from chronic malnutrition. Undernourished children experience respiratory infections, coupled with bouts of diarrhea, intestinal helminth infection, epidemic measles, and more. These co-morbidities make what might be a mild respiratory illness in an otherwise healthy child significantly

more serious in children living in the tropics (Table 128-2).<sup>8</sup> The role of viral URIs, particularly influenza and respiratory syncytial virus, in predisposing individuals to subsequent bacterial infection, predominantly with *Streptococcus pneumoniae* and *Hemophilus influenzae* has emphasized the importance of controlling epidemic influenza in developing nations where vaccines have been historically underutilized.<sup>9</sup>

Acute lower respiratory infections cause most of the respiratory disease-associated deaths and, in terms of years of life

SARS Coronavirus

Modified from Adegbo RA, Obaro SK: Diagnosis of childhood pneumonia in the tropics. Ann Trop Med Parasitol 94:197, 2000.

ESTIMATES OF THE PERCENTAGE OF CHILDREN WHO DIE FROM ACUTE LOWER RESPIRATORY INFECTION BY COUNTRY, 2000

lost (YLL) in sub-Saharan Africa, ranks second only to diarrheal diseases.<sup>10</sup> The most common etiologies of childhood pneumonia in developing countries are summarized in Box 128-2.<sup>11</sup> Although all age groups have some deaths associated with lower respiratory infections, the greatest burden is borne by children, especially those younger than 5 years old, with an estimated 3 to 4 million deaths annually.<sup>12,13</sup> Data from WHO reveal a marked difference in the proportion of deaths in children less than 5 years old caused by ARIs in Europe (11%) and the Americas (14%) versus Africa (22%) and Southeast Asia (19%).<sup>1</sup> Most developed nations of Europe and North America report less than 5% of childhood deaths due to ARIs. Africa not only bears the burden of very high childhood mortality, but also has nations with more than 25% of childhood deaths due to ARIs.<sup>1</sup> The role of co-infection with HIV and/or malnutrition in ARI-associated deaths cannot be overemphasized. Recent WHO data from Botswana, currently the nation with the highest prevalence of HIV infection, revealed that approximately 60% of childhood deaths due to HIV/acquired immunodeficiency virus (AIDS), often associated with respiratory coinfections.<sup>14</sup>

*S. pneumoniae* and *H. influenzae* remain the most important bacterial causes of pneumonia in young children, accounting for 70% of the deaths from pneumonia and neonatal sepsis.<sup>11</sup> The use of *H. influenzae* B and, more recently, pneumococcal conjugate vaccines has dramatically decreased the frequency of these infections in developed countries but, due to their cost, they remain underutilized in the developing nations.<sup>9</sup>

Bacterial antimicrobial resistance has become an increasing problem worldwide, including in the tropics. Lack of antibiotic availability in some areas has led to low prevalence of resistant organisms. Conversely, poorly controlled access to antibiotics and inappropriate use has led to very high levels of resistance in other areas. One study in Uganda identified 95%

of *S. pneumoniae* as penicillin-resistant and 75% of *H. influenzae* as  $\beta$ -lactamase producing. Despite this resistance, there was a good clinical response to ampicillin even among HIV-infected individuals.<sup>15</sup>

Availability of antibiotics in developing nations is quite variable: Many nations have access to less expensive penicillin, ampicillin, chloramphenicol, erythromycin, tetracycline and aminoglycosides, but the more expensive third-generation cephalosporins, fluoroquinolones, and newer macrolides that are commonly used in developed nations are often unavailable.

Common causes of atypical pneumonia, such as *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Legionella* spp., are probably as common in the tropics as they are in temperate areas but have been poorly studied due to difficulty in culturing and the expense of serology. Outbreaks of Legionnaires' disease associated with travel, especially among the elderly, have been reported on numerous occasions. Nearly half the cases of *Legionella* pneumonia in the United Kingdom are travel-associated.<sup>16</sup>

Measles (rubeola) is the most important viral respiratory disease. Measles is associated with significant morbidity and mortality in much of the developing world, with an estimated 40 million annual cases and 800,000 deaths per year, half of which occur in Africa. Most unvaccinated children in endemic areas are infected by age 5.<sup>17</sup> Since the introduction of measles vaccination in 1963, there has been a marked decrease in measles cases and, as of March 2005, no indigenous transmission of measles has occurred in the Americas for over 2 years; WHO has a goal of worldwide eradication by 2015.<sup>17</sup> Death from measles is usually associated with either a primary viral pneumonia or secondary bacterial infection with *S. pneumoniae*, *H. influenzae*, *Staphylococcus aureus*, or secondary viral infection with herpes simplex or adenovirus.

Numerous studies from the 1930s to the present have demonstrated a marked reduction in morbidity and mortality associated with measles infections after initiation of childhood vitamin A supplementation. This is especially evident in refugee settings where malnutrition and a measles outbreak may be the leading cause of death.<sup>18</sup>

Particular settings in the tropics may suggest the role of certain bacterial organisms: Examples are staphylococcal pneumonia complicating measles and varicella, pertussis in areas with inadequate childhood immunization, and *Klebsiella* pneumonia in lower socioeconomic rural settings where alcoholism and malnutrition may play a role. Chronic cavitary upper lobe infiltrates in a patient from Southeast Asia may be misidentified as tuberculosis but actually represent melioidosis, a chronic infection of *Burkholderia pseudomallei*, a soil saprophyte endemic to Southeast Asia and part of Australia (see Chapter 34). Melioidosis is the most common cause of fatal, community-acquired pneumonia at a regional referral hospital in the Northern Territory of Australia. In a series of 252 cases of melioidosis in Australia, half presented with pneumonia and one-quarter were bacteremic, 15% presented with pneumonia and septic shock, and 84% of the septic individuals died.<sup>19</sup> Melioidosis is well documented to occur months to years after exposure and it should remain in the differential diagnosis for those with appropriate exposure who present with chronic, subacute or acute pulmonary disease that may appear to be tuberculosis.<sup>20</sup>

Occupational exposures may suggest an etiology for unusual bacterial pneumonias such as anthrax, Q fever, tularemia, and leptospirosis. Outbreaks associated with Hantaviruses, pneumonic plague, influenza, and SARS corona-virus are all potential etiologies that should be considered. Since all of these rarer causes of pneumonia can be found nearly worldwide to varying degrees, it may be most helpful to query WHO ([www.who.int/csr/outbreaknet/work/en/](http://www.who.int/csr/outbreaknet/work/en/)) or CDC ([www.cdc.gov/travel/outbreaks.htm](http://www.cdc.gov/travel/outbreaks.htm)) websites to get updates about outbreaks of diseases in different countries.

## CHRONIC COUGH

Cough, a common symptom of URIs, is also frequently associated with pneumonia, chronic obstructive pulmonary disease, bronchiectasis, sinusitis, and asthma. URIs are the most common illnesses of travelers to the tropics. Patients will often assume the worst, that they have developed SARS, tuberculosis, or pneumonia, and seek medical evaluation earlier than they may have if they became ill without traveling. Patients usually do not seek medical attention for cough until it has persisted for more than 5 to 7 days and most cough lasting less than two months is associated with relatively benign viral or bacterial etiologies, but may be associated with recent infection with *Ascaris*, hookworm, *Strongyloides*, or schistosomes. Cough persisting for more than 2 months is considered chronic, and a far wider differential diagnosis should be considered, especially in individuals in the tropics or returning from the tropics.<sup>21,22</sup> Table 128-3 lists some considerations for the differential diagnosis of chronic cough. Many of the infectious etiologies for cough are fully described in other chapters.

In developing a differential diagnosis for chronic cough, in-depth inquiry into the patient's travel background and

**Table 128-3 Common Etiologies of Cough of More than 2 Months Duration That Occur Worldwide and Those More Commonly Associated with Exposure in the Tropics**

<ul style="list-style-type: none"> <li>• Allergic and nonallergic rhinitis</li> <li>• Reactive airways disease (asthma)</li> <li>• Chronic obstructive pulmonary disease</li> <li>• Bronchiectasis</li> <li>• Congestive heart failure</li> <li>• Gastroesophageal reflux</li> <li>• Angiotensin-converting enzyme inhibitors</li> <li>• Eosinophilic bronchitis</li> <li>• Recurrent aspiration</li> <li>• Interstitial lung disease</li> <li>• Sarcoidosis</li> <li>• Neoplasm</li> <li>• Tuberculosis</li> <li>• Pneumoconioses</li> <li>• Endemic mycoses</li> <li>• HIV-associated opportunistic infections</li> </ul>	<ul style="list-style-type: none"> <li>• Tuberculosis</li> <li>• Loeffler's syndrome (helminthic pulmonary transmigration)</li> <li>• Schistosomiasis (acute or late stage disease)</li> <li>• Tropical pulmonary eosinophilia (filarial infection with hypersensitivity reaction)</li> <li>• Paragonimiasis</li> <li>• Penicilliosis marneffeii</li> <li>• Paracoccidioidomycosis</li> <li>• Melioidosis</li> </ul>

exposure history must be obtained. A knowledge of which diseases and infectious agents are endemic to the area is also crucial. A short-term traveler to an urban area of the tropics may have only a remote opportunity to have encountered helminths or tuberculosis, whereas those with a long-term travel history to remote areas, and extensive exposure to the local population, have probably had ample opportunity to be exposed to the wide range of infectious agents endemic in the tropics. Some of these same exposure considerations should be applied to those who live in the tropics; an urban office worker is much less likely to have had the constant animal, insect, and freshwater contact of a rice farmer in rural areas.

Tuberculosis should nearly always be considered in the differential of chronic cough if there is associated fever, weight loss, and pulmonary infiltrates, particularly in infants and young children. Schistosomiasis and intestinal helminths should be considered in "eco-tourists," campers, and those who report freshwater exposure as well as rural denizens. Endemic mycoses, melioidosis, and environmental toxins are potential etiologies that should be entertained in the context of the appropriate geographic region and exposure history. Chest radiographs and serology, as well as sputa and stool microscopy, will usually confirm these diagnoses if they have been considered in the evaluation.

A complete blood count with differential should always be obtained, as cough associated with a parasitic infection may have a normal total leukocyte count but a significantly elevated eosinophil count that would guide the diagnostic evaluation (see Chapter 125). Radiographs of the chest are also indicated in evaluation of chronic cough as characteristic radiologic findings are seen with many of the diagnoses. Abnormal chest radiographs in resource-rich nations are often further evaluated

by computed tomography (CT) scan. Although readily available in most developed nations, CT scanners are not available in 40% of the sub-Saharan countries and are not readily available in many other areas as well.<sup>23</sup> Similarly, availability of bronchoscopic evaluation is variable outside developed nations but should be considered if the etiology of cough cannot be determined with less invasive testing. Sputum examination is generally available in most areas. Sputum examination is most important to rule out tuberculosis (TB) and, in contrast to some other diagnostic modalities, microscopists in the developing world are often quite experienced and skilled in reading stains for acid-fast bacteria, protozoa, and helminths. In temperate areas, routine sputa and even bronchoscopic samples are often not examined for fungi, mycobacteria, and parasites. These etiologies, more common in the tropics, should nearly always be considered in the diagnostic evaluation.

## HEMOPTYSIS

Regardless of tropical or temperate exposure, the development of significant hemoptysis nearly always warrants diagnostic evaluation. While trivial hemoptysis with scant streaks of blood is not uncommon with bronchitis, the differential diagnosis should remain broad, especially in those with tropical exposure. While studies of the etiology of hemoptysis vary significantly depending on geographic location and decade of publication, hemoptysis often indicates an underlying serious disease.

Although bronchiectasis and neoplasia are the most common causes of hemoptysis in developed nations, tuberculosis may exceed these noninfectious etiologies in developing nations. Understanding the prevalence of TB in the area where the patient was traveling (or living) is crucial in developing the differential diagnosis. In a 1997 study from Israel of 208 patients presenting with hemoptysis, only 3 (1.4%) were associated with TB.<sup>24</sup> Similarly, in an older U.S. study from Boston in 1952, only 2 (1.9%) of 105 cases of hemoptysis were attributed to tuberculosis.<sup>25</sup> Conversely, in a 2002 study from Turkey of 108 cases of hemoptysis, 18 (17.4%) were associated with tuberculosis<sup>26</sup> and in a 2001 study of 52 patients with hemoptysis from Kuwait, 17 (32.7%) of the cases were attributed to either “old” or active pulmonary TB.<sup>27</sup> A similar study performed in an area with much higher TB rates, such as Afghanistan or sub-Saharan Africa, might find TB in an even greater percentage of patients presenting with hemoptysis than the relatively less affected Turkey and Kuwait.

**Table 128-4 Etiologies of Hemoptysis Worldwide and Those More Commonly Associated with Exposure in Developing Nations**

Worldwide	Developing Nations
<ul style="list-style-type: none"> <li>• Bronchiectasis</li> <li>• Bronchogenic neoplasm</li> <li>• Bronchitis</li> <li>• Congestive heart failure</li> <li>• Blood dyscrasias</li> <li>• Tuberculosis</li> <li>• Endemic mycoses</li> </ul>	<ul style="list-style-type: none"> <li>• Tuberculosis</li> <li>• Endemic mycoses</li> <li>• <i>Echinococcus</i></li> <li>• <i>Paragonimus</i></li> <li>• <i>Entamoeba histolytica</i></li> <li>• Leptospirosis</li> <li>• Melioidosis</li> </ul>

The role of other infectious etiologies such as *S. pneumoniae*, *Haemophilus* spp., melioidosis, endemic fungi, amoeba, and helminthic agents (ascaris, hookworm, *Strongyloides*, *Echinococcus*, and *Paragonimus*) should all be considered in the differential diagnosis based on the location of the exposure and are summarized in Table 128-4.

Work-up of hemoptysis should start with chest radiographs but may require CT scan or bronchoscopy with biopsies to make a definitive diagnosis. Again, informing the microbiology and pathology laboratories of the potential for fungal, mycobacterial, and parasitic disease will ensure that appropriate stains and cultures are performed.

## EOSINOPHILIA ASSOCIATED WITH PULMONARY COMPLAINTS

Patients presenting for medical attention in the tropics, or after returning from a trip to the tropics, not uncommonly (up to 5%) are found incidentally to have eosinophilia.<sup>28</sup> Although generally not considered to be clinically significant until reaching an absolute eosinophil count of greater than 1000, a relative increase in eosinophils on a complete blood count will often lead to pulmonary or infectious diseases consultation. The differential diagnosis and evaluation of eosinophilia is thoroughly reviewed in Chapter 125.

Evaluation of patients with eosinophilia can be very difficult, especially in the absence of significant symptoms to help guide the assessment. A thorough account of both domestic and tropical travel must be included in the history as well as a detailed inquiry into use of prescription drugs, over-the-counter drugs, and supplements as the etiology may be a hypersensitivity reaction as opposed to an infection. There are a host of nonparasitic and even noninfectious etiologies that should be considered in the evaluation and these are considered in Chapter 125. Furthermore, multiple infections with a number of helminths from a shared exposure occur quite commonly. Stool, sputa, and serologic assays are frequently negative during the larval stages in the pulmonary vasculature.

The intestinal helminths most commonly associated with transmigration of their larvae through the lung leading to the eosinophilia, frequently referred to as Loeffler's syndrome, are *Ascaris*, *Strongyloides*, and the hookworms *Necator* and *Ancylostoma*.<sup>29</sup> Larvae penetrate into the alveolar spaces, are coughed into the mouth and then swallowed, thereby completing their journey to the intestinal tract where the adult stages live. *Ascaris* are most likely to be associated with development of significant pulmonary symptoms; hookworm and *Strongyloides* usually cause minimal inflammation during pulmonary transmigration. Loeffler's syndrome occurs 10 to 12 days after ingestion of *Ascaris* eggs (or 5–10 days after penetration of hookworm or *Strongyloides* larva) and, if there are any symptoms, is characterized by development of 5 to 10 days of nonproductive cough, burning substernal chest pain, and, frequently, wheezing and rales. Chest radiograph reveals ill-defined, patchy, homogenous consolidation or, occasionally, a fine miliary pattern. Infiltrates may be unilateral or bilateral, have indefinite borders, and range from a few millimeters to 2 to 3 cm.<sup>23</sup>

The migration of the larvae of *Toxocara canis* or *T. cati* in pulmonary tissues as a manifestation of visceral larva migrans (see Chapter 103) is associated with high levels of eosinophilia,

and may be associated with fever, hepatosplenomegaly, and transient reticulonodular infiltrates.<sup>30</sup>

Schistosomes may be associated with eosinophilia and chest symptoms (see Chapter 116). Especially in nonimmune travelers, acute schistosomiasis (3–8 weeks after schistosome penetration) may be associated with headache, malaise, dyspnea, wheezing, and nonproductive cough, especially while recumbent in bed. These pulmonary symptoms may coincide with the fever (Katayama fever) associated with acute infection, but more commonly present a few weeks after resolution of fever and are associated with marked eosinophilia (approximately 30%–50%), mild to moderate leukocytosis, and liver enzyme abnormalities.<sup>31</sup> Since schistosomes pass through the lung shortly after penetration (5–7 days), the pulmonary symptoms are likely an immune effect triggered in the lung while the organism has become established elsewhere in the host, similar to established intestinal helminths that may also cause pulmonary infiltrates.<sup>32</sup> Chronic pulmonary disease is a complication of established schistosomal infections as ectopic migration of schistosome eggs occurs. This becomes more common in late disease as portal hypertension leads to portacaval shunts and deposition of eggs in the pulmonary vasculature. The granulomatous response to eggs in the pulmonary vessels leads to pulmonary hypertension and eventually cor pulmonale. Finally, some helminths (most importantly *Paragonimus* spp. and *Echinococcus* spp.) establish their adult stage in the lung and may be associated with years of waxing and waning eosinophilia<sup>30</sup> (see Chapters 114 and 117).

## PLEURAL EFFUSION

The etiologies for pleural effusion are protean and include a wide variety of infectious agents from bacterial and viral to protozoal and helminthic. Common noninfectious etiologies such as malignancies, heart or liver failure, collagen vascular diseases, and others predominate in temperate areas. The differential diagnosis of pleural effusion after exposure in the tropics is skewed due to the high prevalence of tuberculosis and HIV-associated disease and the increased incidence of helminthic, protozoal, and fungal infections. In one study from Zimbabwe of 100 consecutive patients with pleural effusion of unknown etiology, TB was ultimately determined as the final diagnosis in 58 of the patients after pleural biopsy was performed.<sup>33</sup> Temperate areas with a high incidence of tuberculosis may also have TB as a common cause of pleural effusion. For example, a large study of 642 pleural effusions in Spain (in an area with high incidence of TB—95 per 100,000) found TB responsible for 25%, neoplasia for 23%, and congestive heart failure for 18%.<sup>34,35</sup> In areas with a low prevalence of TB, pleural effusions are rarely associated with tuberculosis and are much more commonly a sign of malignancy. Table 128-5 summarizes etiologic considerations for pleural effusion worldwide and in a patient with potential exposure in the tropics.

Evaluation of pleural effusion should involve consideration of multiple aspects of the clinical setting. Bilateral pleural effusion in a patient with underlying heart disease returning from the tropics is still likely a pleural transudate related to heart failure. Presence of fever, pleuritic chest pain, and leukocytosis are obvious indicators of potential infectious etiologies and are indications that thoracentesis is indicated.

**Table 128-5 Etiology of Pleural Effusion with Additional Considerations from the Tropics**

Worldwide	Frequency Diagnosed	Additional Etiologies Tropical Regions
Heart failure	<div>Common</div> <div>↕</div> <div>Infrequent</div>	Tuberculosis
Malignancy		Paragonimiasis

Tuberculosis		Toxocarasis
Endemic fungi		Echinococcosis
Nephrotic syndrome		Amebiasis
Idiopathic		
Hypothyroidism		
Drug hypersensitivity		
Asbestosis		
Collagen vascular diseases		
Pancreatitis		

In addition to cell count, differential, pH, chemistries, Gram stain, and bacterial culture that are routinely obtained, additional consideration of mycobacterial or fungal disease should prompt appropriate stains and cultures.<sup>36</sup> If chest radiographs or the clinical scenario are consistent with possible TB, then a large volume of pleural fluid (at least 10 mL) should be centrifuged and the pellet examined with acid-fast (and fungal) stains and culture to increase the diagnostic yield. Adenosine deaminase levels in the pleural fluid, pleural biopsy, and tuberculin skin testing may also be considered.

An effusion with an eosinophilic pleocytosis at pleurocentesis appropriately prompts consideration of helminthic or other exotic etiologies. Although estimates are that 5% to 16% of pleural effusions are eosinophilic (more than 10% of nucleated cells are eosinophils), only a minority of eosinophilic effusions are due to infectious etiologies, and even fewer are due to helminths or protozoa. In most studies, blood or air in the pleural space is most commonly associated with eosinophilic pleural effusions, but malignancy, infection, pulmonary embolus, drug-induced, and asbestos-associated are all frequent.<sup>37,38</sup> The etiology of eosinophilic pleural effusions is summarized in Table 128-6.<sup>38,39</sup> Patients in or from the tropics presenting with eosinophilic pleural effusion (who do not have an identified etiology for the effusion) should also have a sputum examination and culture for fungi and mycobacteria. Sputa and stool should be examined for ova and parasites as well. Bronchoscopy and/or lung biopsy are considerations if the less invasive diagnostic evaluation is unrevealing. If biopsies are performed, it is important to consider evaluating tissue for fungi, mycobacteria, and parasitic etiologies in the microbiology and pathology labs.

Of all the parasitic etiologies, *Paragonimus* spp. infections are the most likely to be associated with a significant eosinophilic pleural effusion. Asian studies have found approximately 50% of cases of paragonimiasis are associated with pleural effusions.<sup>40,41</sup> Findings of pleural pH less than 7.1 and pleural fluid glucose less than 60 are characteristic.<sup>38</sup> Sputa exam with *Paragonimus* spp. ova will then confirm the diagnosis. Further information on *Paragonimus* spp. is included in Chapter 117.

**Table 128-6** *Etiology and Clinical Features of Eosinophilic Pleural Effusions*

Etiology	Clinical Features
Chest trauma or thoracic medical procedure  Malignancy, either primary pulmonary or pleural or metastatic Parapneumonic effusions  Tuberculosis, either pleural TB or associated with pulmonary infiltrates or nodule(s) Endemic fungi such as coccidioidomycosis, histoplasmosis, cryptococcosis, penicilliosis Parasitic infections Paragonimiasis, ascariasis, strongyloidiasis, echinococcosis, filariasis, loiasis, toxocariasis, dracunculiasis, amebiasis, cutaneous myiasis Medication associated Nitrofurantoin, isotretinoin, fluoxetine, warfarin, dantrolene, glipizide, mesalamine, bromocriptine Pulmonary embolism	Presence of air or blood in the pleural cavity Pleural fluid is bloody or straw-colored Increased eosinophils, even in nonbloody effusions Eosinophils appear a month or more after resolution of infiltrate Gram's stain and culture are negative for bacteria Although eosinophils are rarely associated with TB the frequency of pleural effusion due to TB is common in the tropics If living in or traveling from an endemic area  Travel to or living in endemic areas Pleural fluid exam reveals ova, larva or fragments Paragonimiasis is the most common parasitic etiology (associated with pleural pH < 7.1 and glucose < 60 mg/dL) Usually weeks to months after drug administration but may be as short as hours or as long as years.  18% of pleural effusions are eosinophilic Pleuritic chest pain and dyspnea greater than would be expected with size of effusion History of occupational exposure, Pleural effusion is usually the sole radiographic abnormality Up to 50% of asbestos-associated effusions are eosinophilic Most commonly in middle-aged males with small to moderate, unilateral effusion. May be longstanding but associated with a good prognosis. Should prompt consideration of undiagnosed parasitic infections.

Modified from Kalomenidis I, Light RW: How to approach a patient with an eosinophilic pleural effusion. *J Respir Dis* 24:247, 2003.

Despite aggressive evaluation, as many as one-third of eosinophilic pleural effusions remain undiagnosed, but the prognosis for these individuals even if the effusion has been prolonged has been shown to be excellent. There is some suggestion that asbestos-associated pleural effusion is the etiology in many of these undiagnosed cases. This may be even more common in the tropics where occupational exposures may be substantial and personal protective measures may be minimal; patients may not even be aware of their occupational exposure to asbestos.

## TUBERCULOSIS

A discussion of pulmonary disease in the tropics cannot escape the overwhelming impact of tuberculosis on the lives of those in the developing world. Although TB is addressed in-depth in Chapter 36, the importance of including TB in the differential diagnosis of nearly all pulmonary complaints from the tropics cannot be overemphasized.

Approximately 80% of the 8 million new TB cases in the world are from 20 countries, mostly in the developing world. In pediatrics the numbers are even more staggering, with 90% of the cases and 95% of the deaths from TB occurring in developing nations.<sup>2,14</sup> Many of these same nations are also burdened with the highest HIV infection rates. As the two infections act synergistically to cause progression of each, the effects have been devastating, especially in sub-Saharan Africa (see Chapters 76 and 133).

The incidence of multidrug resistance has been a further, relatively recent complication of TB in the tropics. Inadequate

treatment and follow-up has led to gradually increasing levels of drug resistance, thus requiring not only expensive sensitivity testing but also more expensive, and potentially more toxic, therapy.

Numerous studies have documented the frequency of TB in those who have immigrated to developed nations from the tropics. Concerns about travelers visiting areas of high TB endemicity and potential exposures during air travel are frequently raised. The risk of acquiring TB infection among short-term travelers and on flights is actually quite low.<sup>42</sup> Despite commonly held misconceptions about aircraft air systems, the fairly rapid filtering of air released overhead and leaving the cabin near the floor close to the same row removes and dilutes most infectious particles. Despite hundreds of thousands of flights annually, transmission of TB on aircraft has rarely been reported.<sup>42</sup>

In contrast to short-term travelers, those who remain in areas with a high prevalence of TB have rates of infection that approach that of the local population. This was seen most dramatically in long-term Dutch travelers to Africa, Asia, and Latin America, where their risk of infection increased from approximately 10 infections per 100,000 person-years to approximately 2000 infections per 100,000 person-years. Health-care workers with direct patient contact had more than threefold greater risk of TB than other travelers.<sup>43</sup> Obviously, in considering the possibility of tuberculosis in a returning traveler, a new immigrant or a patient in the tropics, it is critical to know the prevalence of TB in the nation of concern as well as contacts with TB, the living situation, and the activity of the individual evaluated.

There is little evidence to support the use of either routine bacillus Calmette-Guérin (BCG) immunization prior to travel or tuberculin skin testing (TST) before and after. Again, consideration of the length of travel, the prevalence of TB in the area, and the activities planned by the individual may make either BCG immunization or TST reasonable recommendations for some individuals.<sup>44,45</sup>

Individuals who immigrate to developed nations have been documented in numerous studies to have a much higher incidence of TB disease than natives of developed nations. Over 50% of cases of TB in the United States and the United Kingdom occur in people born overseas, and the incidence of disease is more than 3 times greater in foreign-born than U.S.-born individuals.<sup>46,47</sup> Approximately 25% of foreign TB cases diagnosed in the United States present within the first year of presentation. The incidence of active TB among political asylum seekers in London was 241 per 100,000, a level 20 times greater than the overall incidence in England.<sup>48</sup> Clearly individuals from developing nations who present with pulmonary complaints, especially chronic cough associated with hemoptysis, weight loss, and night sweats, should have TB considered as one of the more likely etiologies on a differential diagnosis and have chest radiography, possibly a TST, and sputa examination as part of the evaluation. In some cases, the index of suspicion may be so high that empiric therapy with four antituberculous drugs, preferably with directly observed therapy, should be instituted. Since the prevalence of multidrug-resistant TB is significantly higher in many developing nations, use of four drugs and mycobacterial sensitivity profiles should always be used.<sup>49</sup>

### PLASMODIUM-ASSOCIATED PULMONARY FINDINGS

*Plasmodium falciparum* and, to a lesser extent, *P. vivax* have been associated with significant pulmonary involvement

in only a minority of infected patients (see Chapter 90). In contrast to older literature that described “bronchitic” and “pneumonitic” malaria, there is no evidence that malarial infections are associated with a true pneumonitis. More recent studies have demonstrated the development of pulmonary edema during the treatment of falciparum malaria, especially more severe cases. Malaria-associated pulmonary edema is noncardiogenic (high cardiac index and low systemic vascular resistance) and is considered by most authorities to be consistent with the acute respiratory distress syndrome (ARDS) and related to the malaria-associated increase in pulmonary permeability.<sup>50</sup>

While pulmonary edema occurs in less than 1% of all cases of falciparum malaria, it was found in 42% of a series of U.S. soldiers in the Second World War who died of severe malaria.<sup>51</sup> More recently, three of five Marines who returned from Liberia in 2003 with more than 10% falciparum parasitemia developed ventilatory failure and an ARDS-like presentation 48 to 72 hours after initiation of antimalarial treatment and clearance of parasitemia (unpublished personal data). Malaria-associated pulmonary disease should be considered in the differential diagnosis of those returning from a malarious region with unexplained pulmonary edema.

### HIV-ASSOCIATED PULMONARY DISEASE

Like tuberculosis, the prevalence of HIV in many areas of the tropics, especially sub-Saharan Africa, make it an important consideration in the differential diagnosis of pulmonary disease. HIV infection is fully addressed in Chapter 76 and HIV-associated opportunistic infections in Chapter 133.

As stated previously, TB coinfection is clearly the greatest threat to HIV-infected individuals in the tropics. The WHO reports rates of TB/HIV co-infection greater than 250 per 100,000 in a number of sub-Saharan nations.<sup>52</sup>

**Table 128-7** Selected Pathological Findings by Age and HIV Status of Children Dying of Respiratory Illness in Zambia

Pathologic Finding	Age Group								Total
	HIV-1-Positive				HIV-1-Negative				
	0–5 Months	6–11 Months	12–17 Months	18 Months– <16 Years	0–5 Months	6–11 Months	12–17 Months	18 Months– <16 Years

Interstitial pneumonia	5	3	3	4	7	2	1	5	30
Shock lung	11	3	3	7	1	0	0	2	27
Pulmonary edema	4	2	3	1	2	3	2	2	19
Lymphocytic interstitial pneumonitis	2	0	2	5	0	0	0	1	10
Measles	1	1	1	2	0	2	0	0	7

From Chintu C: Lung disease at necropsy in African children dying from respiratory illnesses: A descriptive necropsy study. *Lancet* 360:985, 2002.

Although *Pneumocystis jirovecii* (formerly *P. carinii*) pneumonia (PCP) remains an important pathogen in HIV-associated pulmonary disease, it is not as common in the HIV-infected patients in the tropics as in temperate zones. However, in a study of African children dying from respiratory illness in Zambia, PCP was exceeded only by acute pyogenic pneumonia as the cause of death in children infected with HIV who were under a year old. CMV, TB, and interstitial lung disease were all common findings (Table 128-7).<sup>53</sup>

As described in Chapter 133, the etiology of HIV-associated pulmonary disease in the tropics includes all those seen in temperate areas but the variety of pathogens is more extensive. A few notable geographic considerations are the prevalence of *Penicillium marneffei* and melioidosis in Southeast Asia and Australia, paracoccidioidomycosis in South America, and blastomycosis in areas of Africa, South America, and Asia. These diseases are often erroneously attributed to TB, even in the areas where they are most common. With the frequency of multiple simultaneous pulmonary infections in HIV infection, even in those diagnosed with TB the possibility of additional diagnoses should be considered.

## NONINFECTIOUS ETIOLOGIES OF TROPICAL RESPIRATORY DISEASE

### Tobacco Use in Developing Nations

Estimates are that a half billion of the world's current population will be killed by tobacco, with increasing numbers of deaths in the developing world.<sup>54,55</sup> It is estimated that the prevalence of male smoking exceeds 50% in many parts of Asia and Latin America.<sup>54</sup> Thus, a change in approach to the patient in the tropics with pulmonary complaints will need to occur as more tobacco-related diseases emerge.

### Rheumatic Heart Disease Presenting with Pulmonary Symptoms

Rheumatic heart disease (RHD) continues to be a very common heart problem in the developing world. Incidence rates of RHD as high as 206 per 100,000 and prevalence rates as high as 18.6 per 1000 are described.<sup>56</sup> Pulmonary complaints and fever in the tropics may represent acute rheumatic carditis or bacterial endocarditis complicating prior rheumatic heart damage. Fever, cough, hemoptysis, and shortness of breath may often lead to an incorrect diagnosis of a primary pulmonary infection. Pulmonary hypertension or congestive heart failure with pulmonary edema due to rheumatic heart damage is not uncommonly seen in impoverished countries, where secondary prophylaxis to prevent recurrent RHD episodes is difficult to administer and valve replacements are prohibitively expensive.

### Pulmonary Diseases Caused by Occupational and Environmental Exposures

Discussion of pulmonary disease in the tropics cannot ignore the significant role of environmental exposures in acute and chronic lung disease. Poorly regulated working conditions in agriculture and mining have resulted in substantial burdens of occupationally related and environmental

lung disease in many regions.<sup>57</sup> Although good prevalence data are lacking, it is likely that there are millions of cases of silicosis worldwide<sup>58</sup> and possibly comparable numbers of other lung disorders due to cotton dust (byssinosis),<sup>59</sup> extrinsic allergic alveolitis caused by microbial contamination of agricultural products such as sugar cane, and airway injury from indiscriminant use and poor control of indoor and outdoor air pollutants.<sup>3,60</sup>

There is a dramatic increase in both TB risk and virulence in populations with silicosis, and probably also people with exposure to silica without overt silicosis. In areas where large portions of the (male) population have been historically recruited into mining, as in southern Africa, this risk factor is very broadly disseminated and may account in part for the astronomical rates of TB in that region of the world. In a study of 304 men from Botswana who had been employed in South African mines for a mean of 15 years, 30% had pneumoconiosis and 6.8% had progressive massive fibrosis, and additionally 26% had a history of, or current, tuberculosis.<sup>61</sup>

While adult males are the primary victims of occupational exposures, children and women face increased risk from indoor, nonoccupational exposures due to the use of dung and other biomass fuels for cooking and heating huts and homes. When combusted, these materials emit everything from silica and other minerals to hazardous air pollutants such as oxides of sulfur and nitrogen, resulting in various clinical problems, including silicosis (so-called hut lung in this setting), chronic bronchitis, asthma, and increased risk of respiratory tract infection.<sup>4,60</sup> The most severely affected regions are those with colder climates, such as the sierra region of South America, the mountainous regions of central Asia, and the high plains of Africa.

Ambient air pollution due to rapid urbanization has resulted in levels of ozone, oxides of nitrogen, and other irritants (photo-oxidant pollution) that are much higher than even in the worst cities in Europe and North America. Data from Latin America, India, and China suggest that very high rates of respiratory infection and asthma may be resulting.<sup>3</sup>

## SUMMARY

To summarize, developing a differential diagnosis for a patient presenting with pulmonary complaints after exposure in the tropics requires clinicians to consider a range of infectious and noninfectious etiologies that is extraordinarily broad. Narrowing the differential is possible only with careful review of the exposure history and geographical areas coupled with knowledge of the available diagnostic resources and treatments.

## ACKNOWLEDGMENTS

I appreciate the input of Dr. Michelle Barry who, as author of this chapter in the first edition, provided significant material for this edition and the editing provided by Lori Martin.

# Ocular Disease

EDWARD T. RYAN  
MARLENE DURAND

## INTRODUCTION

Many tropical infectious diseases have ocular manifestations. A number of such infections (i.e., trachoma, onchocerciasis, measles/xerophthalmia, leprosy) are the cause of significant visual loss and blindness worldwide.<sup>1-3</sup> Ocular involvement by tropical infectious diseases may manifest as conjunctivitis, keratitis, uveitis, retinitis, optic neuritis, lesions of the adnexa including ulcerative lesions of the eyelid, or Parinaud's oculoglandular syndrome (an ulceronodular conjunctival/corneal lesion with associated preauricular adenopathy). Tropical infections may also present as proptosis (a forward bulging of the eye itself) or as a conjunctival, intraocular, or orbital "worm."

## VIRAL INFECTIONS

### Adenovirus

Worldwide, adenovirus is probably the most common cause of viral ocular infection.<sup>4-6</sup> Over 40 serotypes of adenovirus have been identified (see Chapter 59). Ocular involvement by adenovirus usually manifests as one of three clinical syndromes: nonspecific follicular conjunctivitis, pharyngoconjunctival fever, or epidemic keratoconjunctivitis. Nonspecific follicular conjunctivitis is the most common manifestation of ocular adenoviral infection. It has been reported with many adenoviral serotypes and is most often mild, self-limited, and nonspecific. Adenoviral conjunctivitis may include petechiae or may more rarely present as hemorrhagic conjunctivitis.<sup>7</sup> Pharyngoconjunctival fever is also a self-limited disease.<sup>8</sup> It is most commonly associated with serotypes 3, 4, and 7. It manifests as acute follicular conjunctivitis that is associated with an upper respiratory tract infection, regional lymphadenopathy, and fever. Mild punctate keratitis may appear. The illness spontaneously resolves over 1 to 2 weeks and is most frequently reported in children.

Epidemic keratoconjunctivitis has the most severe ocular manifestations. It manifests as acute follicular conjunctivitis with a diffuse, superficial, fine "pinpoint" epithelial keratitis. Because of the involvement of the cornea, ocular pain is a prominent feature. Preauricular lymphadenopathy may be present. By the second week of infection, focal or punctate epithelial keratitis can occur (Fig. 129-1).<sup>6</sup> By the second to third week of infection, subepithelial corneal infiltration may be present in 30% to 80% of affected persons.<sup>6</sup> The infiltrates are thought to represent an immunologic reaction, can persist

**FIGURE 129-1** Adenoviral keratoconjunctivitis. Note punctate opacities in the cornea. (From Sanford-Smith J: *Eye Diseases in Hot Climates*, 2nd ed. Oxford, Wright Publishers, Butterworth Heinemann, 1990, plate 4e.)

for months to years, and can result in significant visual disturbances if located within the visual axis. Epidemic keratoconjunctivitis is most frequently associated with adenovirus serotypes 3, 8, 10, 19, 21, and 37.<sup>6</sup> Rarely, a large corneal erosion or conjunctival pseudomembrane can occur.<sup>6,9</sup> Diagnosis is usually one of clinical recognition. Viral cultures, immunofluorescence studies, serologic examinations, and molecular techniques can be employed.<sup>6,7</sup> Treatment is usually symptomatic.<sup>10</sup> Topical steroids should be used only to treat severe and symptomatic subepithelial corneal involvement in epidemic keratoconjunctivitis or if extensive pseudomembrane formation has occurred (and only after concomitant herpetic ocular involvement has been excluded).<sup>6</sup> Adenoviral ocular involvement can be explosively epidemic. Adenoviruses may persist on fomites for as long as 2 months. Contact precautions and disinfection of contaminated equipment and surfaces are required.

### Enterovirus

The enterovirus group includes enterovirus, poliovirus, coxsackievirus, and echovirus (see Chapter 60). Over 70 enteroviruses, 30 echoviruses, and 20 coxsackieviruses have been identified. Ocular manifestations of enteroviral infections include acute hemorrhagic conjunctivitis, cranial nerve dysfunction in acute enteroviral neuropathy, and possibly retinitis.<sup>11</sup>

### Acute Hemorrhagic Conjunctivitis

Acute hemorrhagic conjunctivitis was first recognized as a clinical entity in Africa in 1969. The entity is highly contagious, and a pandemic ensued.<sup>12</sup> Enterovirus 70 and coxsackievirus 24 have been established as major etiologic agents.<sup>12,13</sup> The viruses are spread by hand-to-hand and fomite-to-hand transfer. Respiratory spread may occur. The illness has an incubation period of only 1 to 2 days. Presentation is one of acute conjunctivitis with eyelid edema and lacrimation. Ten percent to 70% of affected persons have some conjunctival

hemorrhages, usually bulbar.<sup>12</sup> Hemorrhagic involvement may be either petechial or involve the entire conjunctiva (Plate 129-1).<sup>12</sup> Mild follicular inflammatory changes can be present. Mild, self-resolving, punctate, epithelial keratitis can occur in a small minority of patients.<sup>12</sup> Preauricular lymphadenopathy is frequent, and mild iritis has been reported. The syndrome is usually short in duration, with resolution beginning within 2 to 4 days of onset and continuing for 1 to 2 weeks. Mild systemic manifestations may include headache, pharyngitis, and coryza in a minority of patients. There are usually no long-term ocular sequelae. Enterovirus-70 acute hemorrhagic conjunctivitis, however, is associated with the subsequent development of polio-like radiculomyelitis.<sup>13</sup>

The neurologic syndrome often presents with lancinating pain, fever, and malaise. The radiculomyelitis occurs 2 to 60 days after the onset of the conjunctivitis and most often presents acutely.<sup>12</sup> Involvement results in flaccid weakness and paralysis that is asymmetrical and areflexic.<sup>12,13</sup> Pleocytosis of the cerebral spinal fluid is present. Cranial nerves can be affected. Extraocular palsies can result. The polio-like syndrome can resolve over months but often results in permanent deficits.<sup>12</sup> By analogy to what is observed in clinical poliomyelitis, the neurologic syndrome has a predilection to occur in limbs that have received an intramuscular injection.<sup>14</sup>

#### Box 129-1 Causes of Selected Types of Conjunctivitis

##### **Hyperacute Conjunctivitis\***

*Neisseria gonorrhoeae*<sup>†</sup>  
*Neisseria meningitidis*<sup>†</sup>

Pneumococci  
*Streptococcus* species  
*Neisseria* species  
*Chlamydia* species  
*Mycoplasma* species (Stevens-Johnson syndrome-associated)  
Adenovirus<sup>†</sup>  
Enterovirus  
*Candida* species

##### **Hemorrhagic Conjunctivitis**

Enterovirus type 70<sup>†</sup>  
Coxsackievirus A24<sup>†</sup>  
Pneumococci  
*Neisseria* species  
*Haemophilus* species  
*Chlamydia* species  
*Borrelia* species  
*Rickettsia* species  
Adenovirus  
Herpesvirus  
Newcastle virus  
Hemorrhagic fever virus (e.g., Ebola virus)  
*Trichinella spiralis*

\*Hyperacute conjunctivitis is defined as a rapidly progressive conjunctivitis with copious purulence.

<sup>†</sup>Common or classic ocular manifestation of infection.

Intramuscular injections should therefore be avoided in the treatment of patients with acute hemorrhagic conjunctivitis.

Diagnosis of acute hemorrhagic conjunctivitis is one of clinical recognition (usually during an epidemic). Viral cultures or serologic assays can be performed. Systemic antibody responses are rarely prominent. It should be recalled that “hemorrhagic conjunctivitis” has been associated with a number of nonenteroviral infectious agents (Box 129-1), including pneumococci, *Neisseria* species, *Haemophilus* species, chlamydia, herpesvirus, and the poultry-associated Newcastle disease virus. Treatment of acute hemorrhagic conjunctivitis associated with enterovirus-7 and coxsackievirus-24 is symptomatic. Strict handwashing procedures and sterilization of equipment should be performed.

#### Poliovirus

Ocular manifestations of poliomyelitis are rare, but they do occur (see Chapter 60). Bulbar poliomyelitis is associated with paralysis of muscle groups innervated by cranial nerves. Five percent to 35% of persons with paralytic poliomyelitis experience bulbar involvement. Although involvement of the IXth and Xth cranial nerves (with pharyngeal paralysis) is most frequent, over 10% of patients with bulbar poliomyelitis have cranial nerve involvement that affects the eyes, orbital musculature, or both. Ocular palsies, ptosis, pupillary disturbances, and ophthalmoplegia can occur. Therapy is supportive.

#### Influenza

The most common ocular manifestation due to infection with influenza virus (see Chapter 59) is anterior uveitis that may occur during acute illness or during convalescence. Conjunctivitis, dacryoadenitis, mild keratitis, chorioretinitis, retinal hemorrhages, retinal edema, cranial nerve dysfunction, and optic neuritis may also occur during influenza, although many of the reports describing such associations predate the availability of confirmatory viral studies. Treatment of influenza is usually symptomatic. Oral amantadine, rimantadine, or selective neurominidase inhibitors may be employed in the treatment of certain debilitated patients. Ocular manifestations are usually mild and self-limited. Topical steroids may be used in the treatment of anterior uveitis. Effective yearly vaccines are available. Aggregation of split virion particles in certain influenza vaccine preparations may cause a self-limited oculorespiratory syndrome that manifests as mild conjunctivitis following parenteral immunization.<sup>15</sup>

#### Measles

Keratitis occurs in all persons with measles (see Chapter 55).<sup>16</sup> Such keratitis occurs within a few days of the outbreak of the skin rash and may persist for months. Slit-lamp examination discloses punctuate epithelial erosions even in patients with measles without eye symptoms. Conjunctivitis with tearing and eyelid edema is also common and usually resolves without any lasting sequelae.<sup>16</sup>

Vitamin A deficiency results in xerophthalmia (conjunctival/corneal epithelial irregularities and xerosis; Fig. 129-2). Acute vitamin A deficiency can be induced by measles in persons with marginal vitamin A stores.<sup>17</sup> Results can be catastrophic.

**FIGURE 129-2** Early xerophthalmia. Corneal and conjunctival xerosis secondary to vitamin A deficiency. (From Sandford-Smith J: *Eye Diseases in Hot Climates*, 2nd ed. Oxford, Wright Publishers, Butterworth Heinemann, 1990, plate 12a.)

Without adequate vitamin A, the punctate epithelial keratitis of measles can coalesce into larger epithelial ulcers (Plate 129-2). Such erosions can become secondarily infected with bacteria or fungi. Corneal scarring may result. Reactivation of herpes simplex keratitis and corneal ulceration may occur.<sup>18</sup> The application of traditional eye medicines or poultices can result in additional ocular damage. Keratomalacia, a marked weakening of the corneal stroma that can result in total melting of the cornea, can occur in persons who are markedly deficient in vitamin A (Fig. 129-3). Worldwide, measles-associated corneal ulceration and scarring result in significant visual loss and blindness (Fig. 129-4).<sup>19,20</sup>

Posterior ocular disease associated with measles includes retinopathy, retinal vessel attenuation, retinal edema, and retinal hemorrhages.<sup>21</sup> Retinal pigmentary changes may persist.<sup>21</sup> Visual acuity may be markedly decreased and, even after resolution of the acute illness, loss of vision may be severe.<sup>21</sup> Involvement of the central nervous system with measles-associated acute encephalitis or subacute sclerosing panencephalitis can be associated with papilledema, chorioretinitis,

**FIGURE 129-3** Measles-associated keratomalacia in a child with vitamin A deficiency. The cornea has completely melted away and only a thin sheet of fibrin covers the iris. (From Sandford-Smith J: *Eye Diseases in Hot Climates*, 2nd ed. Oxford, Wright Publishers, Butterworth Heinemann, 1990, plate 12d.)

**FIGURE 129-4** Child blinded from corneal scarring secondary to measles and xerophthalmia. (From Sandford-Smith J: *Eye Diseases in Hot Climates*, 2nd ed. Oxford, Wright Publishers, Butterworth Heinemann, 1990, cover.)

optic neuritis, optic atrophy, and extraocular palsies.<sup>21</sup> Congenital measles is associated with pigmentary retinopathy and with cataract formation.

Diagnosis of measles is usually one of clinical recognition. Viral culture and antigenic studies can be performed on tissue scrapings or samples in atypical cases. Treatment of uncomplicated measles is usually supportive. A number of studies in the developing world have demonstrated that the routine administration of vitamin A to patients with measles (both among hospitalized individuals and in the community) can lead to a 30% to 80% reduction in measles-associated mortality as well as to a marked reduction in measles-associated morbidity (see Chapter 55).<sup>22,23</sup> A number of dosing regimens have been shown to be equally efficacious.<sup>22,23</sup> Specific ocular therapy should be directed toward preventing the progression and superinfection of corneal ulcers. Antibiotic eye drops/ointments and eye patching may be employed. Uncomplicated cases of measles rarely require specific ocular therapy beyond the use of artificial tears or cold compresses.

## Rubella

Infection with rubella virus can be either acquired or congenital. Acquired rubella often manifests as a systemic viral illness with mild exanthem and lymphadenopathy. The most common ocular manifestation during acquired rubella infection is conjunctivitis, which occurs in 70% of symptomatic patients.<sup>24</sup> Epithelial keratitis occurs in 5% to 10% of infected patients.<sup>24</sup> Corneal stromal involvement, iritis, retinitis, and vasculitis have been reported.<sup>25</sup> Rubella infection that occurs in a susceptible woman in her first trimester of pregnancy has an 80% chance of affecting the fetus.<sup>26</sup> Ocular manifestations may occur in over half of all such neonates with congenital rubella.<sup>27</sup> Retinopathy is the most common manifestation and is characterized by patchy black retinal pigmentary changes.<sup>21,28</sup> Visual acuity is often preserved. Cataracts affect 15% of persons with the congenital rubella syndrome and may be either unilateral or bilateral.<sup>29</sup> Microphthalmia, glaucoma, buphthalmos, retinal neovascularization, and nystagmus can occur.<sup>21</sup> Diagnosis is usually one of clinical recognition. Serological conversion or isolation of virus can confirm the diagnosis.<sup>21</sup> Therapy is supportive. Acute rubella

retinitis appears to respond to systemic steroids.<sup>30</sup> The treatment of ocular manifestations of congenital rubella syndrome may include cataract extraction and antiglaucoma therapy.

## Mumps

Mumps classically presents as parotitis and fever. Orchitis, oophoritis, and pancreatitis can also occur. The most common ocular manifestation is dacryoadenitis, which may occur in up to 20% of persons with acute mumps.<sup>31</sup> Dacryoadenitis may present as edema and erythema of the superotemporal lid and conjunctiva. The gland may be visibly enlarged. Involvement is usually bilateral. Optic neuritis, disciform keratitis, iritis, uveitis, scleritis, and acute glaucoma have been reported.<sup>31</sup> Diagnosis is one of clinical recognition and serology. Therapy is usually supportive. Steroid therapy may be of benefit in optic neuritis, iritis, and acute glaucoma.

## Herpes Simplex Virus

Worldwide, herpes simplex virus (HSV) infection of the eye is a leading cause of visual impairment.<sup>32,33</sup> Ocular involvement can result from infection with either HSV-1 or HSV-2 (see Chapter 57). Primary ocular involvement in children and adults is usually due to HSV-1. Such involvement usually presents as follicular conjunctivitis that may be associated with epithelial keratitis. Vesicular formation on the eyelid and ulcerative blepharitis can occur.<sup>34</sup> Primary ocular involvement in neonates is usually due to HSV-2, usually the result of infection during passage through the birth canal. Ocular manifestations can occur in 15% to 20% of infected neonates and usually develop 2 to 14 days after birth.<sup>21</sup> Almost all HSV-infected neonates with ocular findings have some evidence of skin involvement/vesiculation. Neonatal ocular HSV disease usually presents as nonfollicular conjunctivitis.<sup>35</sup> Keratitis, chorioretinitis, acute necrotizing retinitis, optic neuritis, and iritis can occur. Cataracts, chorioretinal scarring, optic atrophy, and micro-ophthalmia may result.<sup>21</sup>

Non-neonatal ocular involvement by HSV can be due to primary infection as described earlier or can be the result of viral reactivation. The most common manifestation of recurrent HSV ocular disease is epithelial keratitis that coalesces to form a thin-branching, dendritic, ulcerative pattern (Plate 129-3).<sup>34</sup> Lacrimation, photophobia, pain, and blurring of vision are common. The corneal ulceration usually heals within 1 to 3 weeks (more quickly if antiviral therapy is used). Some epithelial ulcers do not completely heal and may undergo recurrent breakdown, despite the inability to document persistence of the virus. These “metaherpetic” ulcers are thought to be multifactorial in origin and can lead to frank corneal perforation. Involvement of the corneal stroma during HSV ocular disease can lead to interstitial keratitis, which may lead to scarring. Neovascularization, limbic vasculitis, corneal “ring” immunologic reactions, disciform keratitis, iridocyclitis, corneal anesthesia, and secondary glaucoma can occur.<sup>34</sup>

Posterior ocular HSV disease is more rare than anterior disease. HSV retinitis can include perivascular sheathing, retinal hemorrhages and edema, vascular occlusion, papilledema, optic neuritis, and the most common manifestation, acute retinal necrosis.<sup>36</sup> HSV-associated encephalitis or meningoencephalitis can result in papilledema, cranial nerve dysfunction,

extraocular palsies, and visual disturbances. HSV retinitis can occur concurrently with HSV encephalitis.<sup>21</sup>

Compared with what is the case in the developed world, ocular HSV disease in the developing world is more likely to present with larger geographic or amoeboid corneal epithelial ulcerations than with classic, thin-branching, dendritic, ulcerative patterns; is more likely to present with bilateral ocular involvement; and is more likely to involve non-neonatal children.<sup>37</sup> These differences may be related to differences in nutritional status and to delay in seeking medical attention. The occurrence of HSV ocular disease has also been well associated with concurrent measles and malaria, possibly because of fever-induced reactivation of HSV disease, concurrent immunologic alterations, or both.

Diagnosis of ocular herpetic involvement is usually one of clinical recognition. The classic corneal dendritic epithelial ulceration pattern may be visualized with fluorescein or rose bengal staining and is most frequently associated with HSV (although it may also occur with varicella zoster virus infection). Viral antigenic assays, molecular techniques, and cultures can be performed.<sup>38</sup> Tzanck preparation of an epithelial scraping can disclose multinucleated giant cells. Seroconversion during primary infection can aid in diagnosis, as can the presence of anti-HSV immunoglobulin M (IgM) antibodies in neonates; however, interpretation of antibody levels in recurrent disease is problematic.<sup>21</sup> A number of antiviral agents are available for the treatment of ocular HSV disease, including trifluridine, idoxuridine, vidarabine, bromovinyldeoxyuridine, and acyclovir. The application of topical antiviral agents combined with gentle débridement or interferon therapy can be employed in the therapy of simple epithelial HSV involvement.<sup>10,39</sup> Treatment with oral acyclovir alone is as effective in most cases. Patients with HSV necrotizing keratitis, interstitial keratitis, disciform keratitis, metaherpetic ulceration, iridocyclitis, and retinitis all require more intensive therapy that may include the use of systemic antiviral agents or steroids.<sup>34</sup> It should be stressed, however, that for most HSV ocular disease, steroid use is contraindicated. Steroids are limited to a number of specific HSV-ocular entities and should be employed only by an eye specialist.<sup>34</sup>

## Varicella Zoster Virus

Infection with varicella zoster virus (VZV) can present in one of two classic patterns: *varicella* (chickenpox) or *zoster* (shingles; see Chapter 57).

### Varicella (Chickenpox)

Ocular involvement during acute varicella is usually one of vesicular lid eruption, conjunctivitis, and keratitis. Approximately 4% of children with varicella experience some ocular involvement. Varicella vesicles can form on the conjunctiva itself and may be associated with marked edema and injection (Fig. 129-5).<sup>8,40</sup> Keratitis may be dendritic. Deep ocular involvement can occur. Disciform keratitis, stromal keratitis, and uveitis have been reported. Rarely, optic neuritis, retinopathy, and cranial nerve palsies can occur. Varicella encephalitis can be complicated by papilledema and extraocular palsies. Congenital varicella infection is rare; however, chorioretinitis, cataracts, and microphthalmia can occur.

**FIGURE 129-5** Chickenpox-associated limbic varicella pock. Note surrounding localized injection. (From Jordan DR, Noel LP, Clarke WN, et al: Ocular involvement in varicella. *Clin Pediatr* 23:435, 1984.)

Diagnosis of acute varicella is usually one of clinical recognition. Tzanck preparation of epithelial scrapings of the base of vesicles can disclose multinucleated giant cells. Viral antigenic assays or culture can be employed in unclear cases. Therapy is usually supportive. Systemic antiviral agents should be employed in immunocompromised persons and adults because the incidence of severe complications is increased in these populations. Antiviral agents include acyclovir, valacyclovir, and famciclovir. Anterior ocular involvement in varicella is usually treated symptomatically. Monitoring for bacterial superinfection should be performed, and epithelial ulcers should be treated with topical antibiotic drops or ointments. Anterior uveitis and deep stromal involvement may be treated with topical steroids, and iridocyclitis should be treated with cycloplegia to lessen the incidence of synechial formation. Retinitis and deep ocular disease should be treated with systemic antivirals, usually intravenously.

## Zoster

The varicella virus can remain dormant in sensory ganglionic neurons. When the virus reactivates along a nerve distribution, it is called shingles or zoster. Reactivation is most frequent in thoracic or trigeminal nerve distributions and is most common in older or immunocompromised persons.<sup>40</sup> Involvement of the ophthalmic branch of the trigeminal nerve ( $V_1$ ) is called zoster ophthalmicus. Such involvement is associated with ocular manifestations in 50% to 70% of affected persons (Figs. 129-6 and 129-7). Involvement of the nasociliary branch of  $V_1$  can produce vesicles on the lateral aspect of the tip of the nose (Hutchinson's sign). Such involvement is associated with ocular manifestations in 85% of affected patients. As in varicella, most ocular disease in zoster involves the anterior segment of the eye. Eyelid involvement can lead to lid scarring with retraction and complicating ectropion, exposure keratitis, or both. Papillary conjunctivitis, epithelial keratitis, stromal infiltrative keratitis, and disciform keratitis can occur.<sup>40</sup> Corneal anesthesia may be pronounced and persistent. Such involvement can predispose affected persons to complicating corneal infections and ulcerations.<sup>40</sup> Corneal scarring can occur (Fig. 129-8). Iridocyclitis (with secondary iris atrophy and secondary glaucoma), optic neuritis, vitritis,

**FIGURE 129-6** Severe, hemorrhagic zoster eruption involving the frontal branch of the trigeminal nerve. (From Pavan-Langston D: Varicella-zoster ophthalmicus. *Int Ophthalmol Clin* 15:177, 1975.)

and retinitis have been reported.<sup>21,40,41</sup> Acute and postherpetic neuralgia can be debilitating.<sup>34</sup>

The retinitis associated with zoster may be more frequent in immunocompromised persons, especially among those with acquired immunodeficiency syndrome (AIDS).<sup>42</sup> The retinitis can be necrotic and can lead to the syndrome of acute retinal necrosis (ARN).<sup>43</sup> VZV is associated with vasculitis, and much of the necrosis, retinitis, and optic neuritis associated with VZV infection is thought to be vascular. Branch artery inclusion can occur.<sup>44</sup> Rare persons can experience ocular VZV involvement in zoster without cutaneous involvement. In such persons, pain in the  $V_1$  nerve distribution may be present. Zoster may be the presenting feature of infection with human immunodeficiency virus (HIV), especially in young persons.

**FIGURE 129-7** Zoster ophthalmicus with involvement of the nasociliary and frontal nerves. Note conjunctival injection and purulent discharge. (From Liesegang TJ: The varicella-zoster virus: Systemic and ocular features. *J Am Acad Dermatol* 11:170, 1984.)

**FIGURE 129-8** Residual corneal scarring, lipid deposition, and corneal thinning after zoster ophthalmicus. (From Liesegang TJ: The varicella-zoster virus: Systemic and ocular features. *J Am Acad Dermatol* 11:172, 1984.)

Diagnosis is usually one of clinical recognition. Tzanck preparation of an epithelial scraping, culture, or viral antigenic studies can be performed in unclear cases. Topical antiviral agents may be applied. Systemic acyclovir, valacyclovir, and famciclovir can decrease the time to healing and may lessen the pain associated with zoster. Foscarnet may also be of benefit.<sup>42</sup> Intravenous therapy should be considered in immunocompromised patients and should be employed in patients with retinitis, ARN, or disseminated zoster.<sup>21,34</sup> Topical steroids can be employed for the treatment of deep anterior inflammatory ocular disease. Cycloplegia can aid in preventing synechial formation. Patients with corneal epithelial defects should receive topical antimicrobial agents to prevent bacterial or fungal superinfection. Systemic analgesia is often required for pain control.

### Acute Retinal Necrosis

ARN is a syndrome characterized by retinal vasculitis, retinal necrosis, and vitritis. The syndrome may present with decreased vision, uveitis, or ocular pain.<sup>21,43,45</sup> It has been most frequently associated with herpes family viruses, most commonly with VZV and HSV. Visual loss can be severe, and involvement can be bilateral. Prolonged systemic acyclovir should be employed, with initial therapy being administered intravenously.<sup>45</sup> Systemic steroids are sometimes employed.<sup>45</sup> Surgery is often required to treat retinal detachments secondary to vitreal retractions. Patients immunocompromised with HIV may have a similar syndrome of progressive outer retinal necrosis associated with herpetic involvement. Uveitis and vitritis are usually much less pronounced in such persons.<sup>45</sup>

### Cytomegalovirus

Cytomegalovirus (CMV; see Chapter 57) infection is usually subclinical and can be acquired either congenitally or during later life. Approximately 40% of newborn infants born to mothers who sustain primary CMV infection during

pregnancy acquire congenital infection. Ten percent to 15% of such newborns have clinical manifestations, and approximately 20% to 30% of infants with severe cytomegalic inclusion disease have chorioretinitis.<sup>46</sup> Optic atrophy and, rarely, anophthalmia may occur.<sup>21,46</sup>

Acute infection acquired after gestation in immunocompetent persons is most often asymptomatic. A mononucleosis-like syndrome can occur and can be associated with mild, nonspecific conjunctivitis.<sup>47</sup> Rare cases of retinitis have been reported.<sup>48</sup> Most symptomatic disease, however, occurs in immunocompromised persons, especially in those with AIDS. AIDS-associated CMV ocular disease occurs almost exclusively in persons whose CD4 cell count is less than or equal to 50 cells/mL.<sup>49</sup> In such persons, CMV classically involves the eye with hemorrhagic necrotizing chorioretinitis (Fig. 129-9). The retinitis often follows a perivascular distribution. The retinitis is progressive and can be bilateral. Retinal detachments are frequent. Optic neuritis can occur and can result in optic atrophy.<sup>21</sup> Punctate keratitis and iridocyclitis can occur. Up to 40% of individuals with untreated AIDS will develop ocular CMV disease.

Diagnosis of ocular CMV disease is usually one of clinical recognition. Systemic CMV disease can be diagnosed by viral antigenic assays, serologic or molecular assays, and culture. CMV retinitis needs to be distinguished from acute retinal necrosis, VZV retinitis, progressive outer retinal necrosis, and toxoplasmosis-associated retinitis, among other entities. CMV retinitis in immunocompromised patients is progressive without therapy. The antiviral agents ganciclovir, valganciclovir, foscarnet, and cidofovir are the mainstays of therapy. These agents are virostatic and, after an initial course of induction therapy, maintenance therapy must be continued. Even after an initially favorable clinical response is achieved, reactivation of CMV chorioretinitis almost always occurs if the severe immunocompromised state continues.<sup>50</sup> In the case of CMV retinitis associated with advanced HIV disease, immune reconstitution following initiation of antiretroviral therapy has been associated with an immune recovery uveitis.<sup>51</sup> Maintenance anti-CMV treatment has been successfully discontinued in individuals with HIV whose CD4 count

**FIGURE 129-9** Cytomegalovirus-associated retinitis. Note hemorrhagic necrosis of the retina with exudates and periphlebitis. (From Rao NA: Acquired immunodeficiency syndrome and its ocular complications. *Indian J Ophthalmol* 42:57, 1994.)

**FIGURE 129-10** A child with Epstein–Barr virus–associated Burkitt's lymphoma involving the left orbit and maxilla. (From Sandford-Smith J: *Eye Diseases in Hot Climates*, 2nd ed. Oxford, Wright Publishers, Butterworth Heinemann, 1990, p 210.)

increases to at least  $75 \times 10^6$  cells/mL who have been taking highly active antiretroviral treatment for at least 18 months.<sup>52</sup>

Oral valganciclovir may be used for maintenance therapy, as can a sustained-release ganciclovir intraocular implant.<sup>53,54</sup> Repetitive intravitreal injections of ganciclovir can also be employed in both induction and maintenance therapies of CMV retinitis.<sup>55</sup> Such local modalities of therapy, however, result in minimal if any systemic drug levels. In addition, such therapies neither prevent nor treat ocular disease in the contralateral eye (or systemic CMV disease). Management of retinal detachment in CMV retinitis may entail primary vitrectomy and installation of silicon oil to act as a tamponade (with or without scleral buckling).<sup>56</sup>

### Epstein–Barr Virus

Epstein–Barr virus (EBV) is worldwide in distribution (see Chapter 57). Persons in developing nations are most often infected as children.<sup>21</sup> While most infections are relatively asymptomatic, EBV is the leading cause of infectious mononucleosis. The most common ocular manifestation of EBV infection is transient mild conjunctivitis that is often follicular, can be unilateral, and occurs in 2% to 40% of persons with infectious mononucleosis. Superficial and stromal keratitis have also been reported.<sup>57</sup> EBV may also play a role in the dry eye of Sjögren's syndrome and in the lymphocytic infiltration of corneal endothelium in the iridocorneal endothelial syndrome.<sup>57</sup> EBV infection may be associated with uveitis, iritis, retinitis, choroiditis, optic neuritis, papilledema, dacryoadenitis, cranial nerve palsies, and Parinaud's oculoglandular syndrome.<sup>57–60</sup> EBV associated with Burkitt's lymphoma, a disorder most frequently reported in children in sub-Saharan Africa (but worldwide in distribution), most often manifests

as a maxillary/orbital mass and can present with proptosis (Fig. 129-10).

Heterophile or monospot antibody assays can be employed in the diagnosis of acute EBV, and serologic assays to various EBV antigens can be employed in unclear or in chronic cases.<sup>21</sup> Treatment of infectious mononucleosis is usually supportive. Optimal therapy for ocular manifestations is unclear. Antiviral agents do not appear to alter the clinical course substantially. Extensive inflammation has been treated with steroid preparations.

### Human Immunodeficiency Viruses

HIV-1 and HIV-2 are the causative agents of AIDS (see Chapter 76). The majority of patients with untreated AIDS have ocular manifestations. HIV has been isolated from tears, conjunctiva, cornea, retina, retinal vessel endothelium, and vitreous.<sup>21</sup> Ocular manifestations of HIV infection can be due to HIV itself or to secondary opportunistic ocular infections. The most common ocular involvement resulting from HIV itself is HIV retinopathy (Fig. 129-11). HIV retinopathy occurs in over two-thirds of patients with untreated AIDS; is characterized by the formation of retinal cotton wool spots, microaneurysms, and hemorrhages; and appears to be due to a microvasculopathy.<sup>61,62</sup> Cotton wool spots represent areas of ischemia in the nerve fiber layer and are usually oriented along vascular arcades. The pathogenesis of the vasculopathy is not well understood. The frequency of HIV retinopathy increases as the level of immunologic suppression increases, but HIV retinopathy usually remains asymptomatic as long as the macula is not affected. Some persons infected with HIV develop large-vessel vasculopathy for unclear reasons. The consequent, retinal vaso-occlusion can involve central or branch retinal veins and visual loss can be severe. HIV infection can also be associated with a primary optic neuropathy and an infiltrative lymphocytosis syndrome.<sup>63</sup>

Compared with what occurs with primary HIV eye involvement, HIV-induced ocular opportunistic infections (see Chapter 133) are often symptomatic, may be the presenting feature of infection by HIV, and can result in severe

**FIGURE 129-11** Human immunodeficiency virus–associated retinopathy. Note retinal cotton wool spots and hemorrhages. (From Rao NA: *Acquired immunodeficiency syndrome and its ocular complications*. *Indian J Ophthalmol* 42:57, 1994.)

visual loss or blindness. The frequency of specific ocular opportunistic infections varies by geographic location and patient population but may include such entities as CMV, toxoplasmosis, tuberculosis, syphilis, cryptococcosis, histoplasmosis, and HSV infection, among others.<sup>64–66</sup> Such infections can result in chorioretinitis, uveitis, optic neuritis, and keratitis. AIDS-associated meningitis or encephalitis may also be associated with cranial nerve dysfunction and ocular palsies. Involvement of the central nervous system or orbit by HIV-associated lymphoma may result in papilledema or proptosis, respectively.

A number of distinct ocular entities also appear to occur in persons infected with HIV. Infectious multifocal choroiditis is a term used to describe a choroidal infection, usually caused by a systemic opportunistic infection with *Pneumocystis jiroveci* (previously *Pneumocystis carinii*), *Cryptococcus neoformans*, *Mycobacterium tuberculosis*, *Histoplasma capsulatum*, or *Mycobacterium-avium-intracellulare* complex, among others (see Chapter 133). Progressive outer retinal necrosis is a posterior ocular syndrome that occurs in patients with AIDS and is thought to be related to herpes viral infection.<sup>67</sup> There is no effective treatment and visual outcome is usually dismal. An ocular vasculopathy that occurs in patients with AIDS may also be associated with conjunctival microvascular changes that may manifest as dilated, short segments of conjunctival vessels. Coinfection with *Molluscum contagiosum* virus can also lead to follicular conjunctivitis. Ocular involvement in patients with AIDS can be extensive and bilateral. Kaposi's sarcoma of the eyelid, conjunctiva, and orbit has also been reported in patients with AIDS. Ocular surface squamous neoplasia may also be associated with HIV infection.<sup>68</sup> Treatment of HIV retinopathy is directed toward systemic anti-HIV therapy, and treatment of opportunistic ocular infections is targeted to the specific pathogenic entity.

### Human T-Cell Lymphotropic Virus Type I

Human T-cell lymphotropic virus type I (HTLV-I) infection is usually asymptomatic; however, a minority of persons infected with HTLV-I develop adult T-cell leukemia/lymphoma (ATCLL) or tropical spastic paraparesis/HTLV-I-associated myelopathy (TSP/HAM; see Chapter 76). A number of ocular manifestations have been reported in patients symptomatically or asymptotically infected with HTLV-I.<sup>69</sup> Similar to what is observed in persons infected with HIV, asymptomatic retinal cotton wool spots and transient retinal exudates and hemorrhages have been observed.<sup>70</sup> Uveitis and interstitial keratitis are the most frequent symptomatic ocular manifestation of HTLV-I infection.<sup>69–72</sup> The uveitis appears to be due to the presence of virally infected T cells in the eye, is often unilateral, and can be anterior, posterior, or panuveal.<sup>69</sup> Keratoconjunctivitis sicca, vitritis, retinal vasculitis, retinal exudates, and retinal hemorrhages have been reported.<sup>69,71,73</sup> Ocular involvement in persons with TSP/HAM can include uveitis and vasculitis as well as neurophthalmologic manifestations. Ocular involvement in persons with ATCLL can include direct lymphomatous or leukemic involvement of the eye. Lymphoma/leukemia of the eyelid, orbit, retina, and vitreous, as well as a lymphoma/leukemia that diffusely infiltrates all ocular structures have been reported.<sup>70</sup> Patients with

ATCLL often die of opportunistic infections, and CMV retinitis has been reported in patients with HTLV-I and ATCLL.<sup>70</sup> Diagnosis of HTLV-I infection is usually based on a serologic antibody assay (although viral studies may also be performed).<sup>69</sup> No treatment is indicated in persons with asymptomatic HTLV-I infection. Topical or systemic steroids can be employed in persons with HTLV-I uveitis.<sup>69</sup> Opportunistic infection should be treated. Antiretroviral agents are not effective.

### Viral Encephalitis

Encephalitis can be caused by a number of viruses, including herpesviruses and arboviruses, the latter including West Nile virus, Venezuelan equine encephalitis virus, western equine encephalitis virus, Japanese encephalitis virus, Murray Valley encephalitis virus, Rocio virus, and Oropouche virus, among others (see Chapters 57, 72, and 74). Ocular manifestations during encephalitis are rarely reported; however, elevated intracranial pressure can result in papilledema. Encephalitis involving brainstem structures can result in disorders of ocular motility, and diffuse encephalitis can result in cortical visual disturbances.

Specific ocular involvement is associated with Rift Valley fever virus (see Chapter 67).<sup>74</sup> The majority of patients with Rift Valley fever present with an acute influenza-like illness that may be biphasic. In 1% to 5% of affected persons, however, hemorrhagic manifestations, encephalitis, or chorioretinitis can occur. Ocular involvement may be immunologically mediated. Clinical features of hemorrhagic fever, encephalitis, and retinitis usually do not overlap in the same individual. Ocular disease includes retinal vasculitis, retinal hemorrhages, and retinitis. Retinal detachment, optic atrophy, vitreal hemorrhages, and blindness can occur.<sup>74</sup> Involvement may be unilateral or bilateral.<sup>74</sup> Conjunctivitis, keratitic precipitates, and uveitis have been reported.<sup>74</sup> Diagnosis is usually one of clinical recognition of community-level symptoms of fever, hemorrhage, encephalitis, and blindness, often with a simultaneous occurrence of an epizoonosis in livestock such as sheep, cattle, or camels. Serologic assays are available, and viral cultures can be performed. Treatment is usually supportive.

West Nile virus infection has been associated with multifocal chorioretinitis, occlusive retinal vasculitis, optic neuritis, uveitis, and vitritis.<sup>75–79</sup> Acute flaccid paralysis of facial and ocular muscles can result in diplopia.<sup>80</sup>

### Viral Hemorrhagic Fevers

Infections with a number of viruses can lead to hemorrhagic manifestations. In some persons, Rift Valley fever can itself present with hemorrhagic manifestations as opposed to being associated with encephalitis or retinopathy. Other hemorrhagic fever viruses include dengue fever, yellow fever, Lassa fever, Kuyasanur Forest disease, Congo–Crimean hemorrhagic fever, Junin, Machupo, hantaviruses, and Marburg and Ebola viruses, among others (see Chapters 65–73). Ocular involvement in hemorrhagic fevers is usually a manifestation of a systemic bleeding diathesis. Endothelial vascular and rheologic abnormalities can lead to hemorrhagic involvement of the conjunctivae and retina. Nonspecific eye pain may be a prominent presenting feature of dengue fever, and hemorrhagic

conjunctivitis has been reported in patients infected with Ebola virus.<sup>81</sup> A specific ocular association has been recognized with Puumala virus in the Scandinavian hantavirus-associated hemorrhagic fever and renal syndrome, nephropathia epidemica.<sup>82</sup> Transient myopia is the most frequent ocular manifestation and relates to forward movement of the ocular anterior diaphragm and thickening of the lens.<sup>83</sup> Eyelid edema, chemosis, conjunctival injection, conjunctival hemorrhage, iritis, acute glaucoma, and retinal edema and hemorrhages have also been reported.<sup>84</sup> Diagnosis can be made by serologic antibody assay. Ocular involvement in nephropathia epidemica usually resolves spontaneously.<sup>82</sup>

## Hepatitis Viruses

Hepatitis can be caused by a number of viral entities and can lead to jaundice (see Chapter 64). The conjunctiva is one of the most sensitive areas of the body for detecting jaundice. Acute viral hepatitis B can itself be associated with immune-complex deposition during the icteric phase of illness, and posthepatitis polyneuritis has been reported (including Guillain-Barré syndrome). Cranial nerves involved by neuritis can result in extraocular palsies. Retrobulbar optic neuritis has been reported in a patient recovering from hepatitis B. Immune-complex deposition resulting from chronic active hepatitis B or C infections can result in a variety of clinical vasculitic entities. Uveitis associated with chronic active hepatitis B may occur. Chronic hepatitis C infection is associated with a dry eye syndrome similar to a Sjögren's syndrome and/or ischemia retinopathy caused by hepatitis C–induced vasculitis or treatment with interferon.<sup>85,86</sup> Diagnosis of acute and chronic hepatitis is usually based on serologic antibody assays or detection of virus. Acute viral hepatitis is treated supportively; chronic active hepatitis may respond to antiviral agents and systemic interferon therapy, the latter itself associated with formation of cotton wool spots, retinal flame hemorrhages, and intraocular hemorrhages.<sup>87,88</sup> Patients with diabetes may be most susceptible to interferon-associated retinopathy and permanent visual loss during treatment for hepatitis C infection.<sup>86</sup>

## Rabies

Ocular structures may be involved during rabies (see Chapter 75). Rabies secondary to animal bites of the face may be associated with facial paralysis and mydriasis. Retinitis and retinal vasculitis can occur with direct viral destruction of retinal ganglion cells and inflammation of the ciliary bodies and choroid have been reported. Human-to-human transmission of rabies has only occurred through corneal transplantation.<sup>89</sup> There is no specific treatment for rabies. Effective active and passive immunization is available for postexposure prophylaxis.

## Lymphocytic Choriomeningitis Virus

Lymphocytic choriomeningitis virus (LCM) is excreted into the urine and feces of infected rodents. Infection in humans may be influenza-like with concomitant meningitis. Evaluation of cerebrospinal fluid usually discloses a lymphocytic pleocytosis; hypoglycorrhacia may be present.

Chorioretinitis may be present. Congenital infection with LCM may result in a chorioretinopathy (that mimics that seen in toxoplasmosis) and neurological sequelae.<sup>68,90</sup> Diagnosis is usually based on serologic or molecular techniques. Treatment is supportive.

## BACTERIAL INFECTIONS

### Chlamydiae

There are three chlamydial species that are currently recognized to infect humans: *Chlamydia trachomatis*, *C. pneumoniae*, and *C. psittaci* (see Chapters 47–49). On the basis of antigenic differences, *C. trachomatis* is divided into various immunotypes. Immunotypes A to C are most commonly associated with trachoma. Immunotypes D to K are most commonly associated with genital tract disease (and less frequently with neonatal ocular infections and adult inclusion conjunctivitis). Immunotypes L<sub>1</sub>, L<sub>2</sub>, and L<sub>3</sub> are responsible for lymphogranuloma venereum (LGV).

### Trachoma

Trachoma, caused by *C. trachomatis* A to C, is the leading infectious cause of blindness worldwide (see Chapter 47).<sup>47</sup> *C. trachomatis* A to C is transmitted by direct contact. Spread of disease is often intrafamilial. Unhygienic practices, aridity, crowding, low socioeconomic status, and the presence of flies have all been identified as important epidemiologic risk factors for developing trachoma. Trachoma occurs predominantly in rural communities of developing nations.

Active trachoma is predominantly a disease of children. Following direct deposition, the organism infects columnar epithelial cells of the conjunctiva. After an incubation period of 5 to 7 days, chronic follicular conjunctivitis of varying severity can result (Figs. 129-12B and 129-12C). Inflammation may be intense, with marked conjunctival edema, conjunctival papillae, and lymphoid folliculitis. Preauricular lymphadenopathy rarely is present. Superficial keratitis can occur. Rupture and scarring of limbic follicles can lead to a semilunar pattern known as Herbert's pits. Untreated infection may resolve over weeks to months. Long-term ocular sequelae from a single episode of *C. trachomatis* A to C conjunctivitis are often minimal. Ocular pathology and morbidity are due to recurrent episodes of conjunctival infection.<sup>91–93</sup> The upper tarsal conjunctiva is most severely affected. Recurrent infectious episodes can lead to eyelid scar formation and cicatrization (Fig. 129-12D). The inflammation and scarring can impede lacrimal tear production and can lead to a decrease in the number of mucus-producing goblet cells. The resultant corneal dryness can lead to additional epithelial breakdown. The cicatrization may lead to retraction of the eyelids inward (entropion; Fig. 129-13). Eyelashes can then sweep directly over the cornea and conjunctival surfaces (trichiasis; see Figs. 129-12E and 129-13). Trichiasis can lead to epithelial breakdown, erosion, ulcerations, inflammatory responses, pannus formation, neovascularization, and scarring (Figs. 129-12F and 129-14). This corneal scarring is the primary cause of trachoma-associated blindness.<sup>92</sup> The World Health Organization's categorization system delineates the various stages/manifestations of

**FIGURE 129-12** Trachoma—World Health Organization classification system. *A*, Normal tarsal conjunctiva. *B*, Trachomatous inflammation—follicular (TF). *C*, Trachomatous inflammation—intense (TI). *D*, Trachomatous scarring (TS). *E*, Trachomatous trichiasis (TT). *F*, Corneal opacity (CO). (From Thylefors B, Dawson CR, Jones BR, et al: A simple system for the assessment of trachoma and its complications. *Bull World Health Org* 65:481, 1987.)

ocular involvement during trachoma (Box 129-2 and Fig. 129-12).

Although most active ocular infections occur during childhood or adolescence, most visual loss and blindness occurs in adults (because of the chronic nature of the ocular damage and the requirement for repetitive acute infections; Fig. 129-15). Bacterial superinfection is not uncommon. Diagnosis is usually one of clinical recognition. Laboratory confirmation can be obtained. Culture is the gold standard

of diagnosis of chlamydial infections but requires mammalian cell lines, is often impractical, and is often negative when performed on patients with end-stage trachomatous damage. Giemsa staining can be performed on conjunctival scrapings and can disclose *Chlamydia*-associated inclusion bodies in epithelial cells, but this method is insensitive in trachoma. Monoclonal antibodies have been developed that react with chlamydial antigens. Immunofluorescent assays and enzyme-linked immunosorbent assays (ELISAs) are available.

**FIGURE 129-13** Trachoma-associated entropion and trichiasis. Note inturning of the upper and lower eyelids. The eyelashes of the lower eyelid are present, but completely inturned. (From Sanford-Smith J: *Eye Diseases in Hot Climates*, 2nd ed. Oxford, Wright Publishers, Butterworth Heinemann, 1990, plate 7b.)

Molecular techniques are also available.<sup>94</sup> Compared with culture techniques, these assays have over 90% sensitivity and specificity. Serologic evaluation for the presence of antichlamydial antibodies can also be employed on blood or tissue samples but is more frequently employed in nontrachomatous chlamydial infection. Tear antibody evaluations may have their greatest utility in late-stage trachomatous disease. It is important to note, however, that many persons with clinical evidence of trachoma do not have laboratory evidence confirming the presence of chlamydial organisms. This is the case even in patients with early trachomatous disease, underscoring the role that the inflammatory response plays in the clinical manifestations of trachoma.

Treatment of trachoma can be directed toward an individual patient or at a community-mass treatment level. Community education in hygienic and behavioral modifications can prevent the chronic and repetitive infections. Individuals and the community can be treated with a number

**FIGURE 129-14** Trachoma-associated corneal pannus formation and neovascularization. (From Choyce DP: *Tropical eye disease*. *Int Ophthalmol Clin* 7:473, 1967.)

**FIGURE 129-15** An adult with entropion, trichiasis, corneal ulceration, pyogenic infection, and blindness due to lifelong trachoma. (From Schwab L, Whitfield R Jr, Ross-Degnan D, et al: *The epidemiology of trachoma in rural Kenya*. *Ophthalmology* 102:476, 1995.)

of treatment regimens. Although prolonged topical therapy is efficacious, compliance is often poor.<sup>10,95</sup> Studies have demonstrated that single-dose oral azithromycin, 20 mg/kg, is equivalent to topical therapeutic regimens.<sup>95–97</sup> The complications of established trachoma can be treated by surgical correction of inturned eyelids.<sup>98</sup> This simple surgical technique can be performed by persons without formal medical training.<sup>99</sup> Epilation of eyelashes may exacerbate the problem because the regrowing eyelash stubs can be abrasive to the corneal surface. Cauterization of the follicular stub may prevent regrowth. For established corneal scars or blindness, corneal transplantation is theoretically possible but often impractical. The degree of conjunctival/corneal scarring and destruction

### Box 129-2 Trachoma: World Health Organization Categorization

- Trachomatous inflammation—follicular (TF): Presence of at least five follicles in the upper tarsal conjunctiva (see Fig. 129-12B)
- Trachomatous inflammation—intense (TI): Obscuring of at least half of the normal deep tarsal vessels by a pronounced inflammatory thickening of the upper tarsal conjunctiva (see Fig. 129-12C)
- Trachomatous scarring (TS): Scarring of the tarsal conjunctiva (see Fig. 129-12D)
- Trachomatous trichiasis (TT): At least one eyelid rubbing on an eyeball (or evidence of self-epilation due to trichiasis) (see Fig. 129-12E)
- Corneal opacity (CO): Visible corneal opacity over the pupil (see Fig. 129-12F)

also limits its utility. If part of the cornea remains clear and unscarred, a partial iridectomy may restore vision.

### **C. trachomatis Nontrachoma Ocular Disease**

#### **Ophthalmia Neonatorum**

*C. trachomatis* immunotypes D to K, common causes of genital disease, including urethritis, cervicitis, and epididymitis (see Chapter 48), can also cause ocular disease. Neonates can be infected during passage through the birth canal, and *C. trachomatis* is one of the most common causes of ophthalmia neonatorum (along with *Neisseria gonorrhoeae*). Other causes of ophthalmia neonatorum include *Streptococcus*, *E. coli*, and other gram-negative organisms.<sup>100</sup> Ophthalmia neonatorum occurs in 1% to 2% of newborns in developed nations, and in 10% to 20% of infants born in developing nations that do not employ prophylactic measures.<sup>101,102</sup> Prophylaxis can be achieved with application at the time of birth of topical silver nitrate or tetracycline and can reduce the incidence of ophthalmia neonatorum by 60% to 70%.<sup>101,102</sup> Approximately 20% to 30% of neonates exposed to *C. trachomatis* during birth develop conjunctivitis, and 10% to 20% develop pneumonitis.<sup>103</sup> The conjunctival presentation is one of a diffuse papillary reaction with lacrimation that occurs between 5 and 14 days after birth. Eyelids are swollen, and hyperemia is present. Discharge may be purulent, and pseudomembranes can form.<sup>104</sup> The conjunctivitis is nonfollicular because the immature immune system of neonates is unable to generate follicles. After 6 to 8 weeks, follicles can form, and chronic infection may present at this time as follicular conjunctivitis.<sup>104</sup> Keratitis has been reported. Conjunctival scars and corneal neovascularization can occur.

*C. trachomatis* is not only present in ocular structures of affected neonates but may also be found in the nasopharynx, vagina, and rectum. The systemic nature of the infection (and the risk of developing pneumonitis or autoreinoculation) negates topical therapy as a sole therapeutic intervention. Untreated, the ocular disease slowly resolves over weeks to months. Diagnosis may be confirmed by conjunctival scrapings with culture and Giemsa staining. Giemsa staining for the detection of chlamydial inclusion bodies may have a sensitivity of over 90% in ophthalmia neonatorum. Immunofluorescent or ELISA antigenic assays are usually performed.<sup>102</sup> Molecular techniques may also be employed. Serology is often not helpful.<sup>105</sup> Tear antibody assays may be of benefit.<sup>106</sup> Tetracyclines are contraindicated in infants. Erythromycin is usually employed. Topical therapy may be added. Repeated courses of therapy may be required. The mother and her sexual partners require systemic therapy, even if asymptomatic.

#### **Adult Inclusion Conjunctivitis**

*C. trachomatis* D to K can also cause inclusion conjunctivitis in children, adolescents, and adults. Ocular involvement results from direct inoculation of infectious genital secretions. Genital infection is most frequently asymptomatic. Ocular involvement is often unilateral. Conjunctival involvement is usually follicular, and onset is usually acute. Preauricular adenopathy may be present. Discharge is minimal, and pseudomembranes that may be present in neonates

do not form in adults.<sup>104</sup> Epithelial keratitis, subepithelial opacities, anterior uveitis and corneal vascularization can occur. Untreated, the conjunctivitis may be chronic and usually resolves over months. Diagnosis can be made by culture or Giemsa staining of conjunctival scrapings; however, a direct immunofluorescent assay is usually employed. Molecular techniques are also available.<sup>107</sup> Examination of the genital tract for chlamydial infection and other concomitant sexually transmitted diseases must be performed. Sexual partners need to be appropriately evaluated and treated. Treatment is systemic, with doxycycline or tetracycline employed in nonpregnant adults.<sup>10</sup> Children and pregnant women should be treated with systemic erythromycin. Concomitant sexually transmitted diseases need to be treated, and follow-up evaluation should be performed.

#### **Lymphogranuloma Venereum**

LGV is a sexually transmitted disease caused by *C. trachomatis* immunotypes L<sub>1</sub>, L<sub>2</sub>, or L<sub>3</sub> (see Chapter 48). Ocular involvement during LGV is rare but described. Keratoconjunctivitis may include fleshy vascularization of the conjunctiva or marginal cornea. Parinaud's oculoglandular syndrome with preauricular adenopathy, and small corneal ulcerations, episcleritis, iridocyclitis, uveitis, and optic neuritis may occur.<sup>104,108,109</sup> Granulomas may involve the orbit or eyelid, and scarring and blockage of lymphatic drainage may result in eyelid elephantiasis.<sup>104</sup> Diagnosis may occasionally be confirmed by culture; however, LGV is usually diagnosed by serologic assay employing complement fixation or microimmunofluorescence.<sup>110</sup> Therapy involves systemic doxycycline, tetracycline, or erythromycin, and prolonged courses may be required.<sup>110</sup>

#### **Chlamydia psittaci**

*C. psittaci* is the cause of psittacosis or ornithosis (see Chapter 49). Uncommon ocular manifestations have included follicular conjunctivitis, uveitis, and keratitis that may be epithelial or interstitial. Serologic assay of antibody levels, including complement fixation titers, is usually employed for diagnosis. *C. psittaci* should be treated with systemic tetracycline or doxycycline.

#### **Reiter's Syndrome**

The classic triad of Reiter's syndrome includes conjunctivitis, urethritis, and arthritis. Characteristic skin, mucous membrane, and bone lesions can occur. The syndrome may be accompanied by keratoderma blennorrhagica (red-brown papular/vesicular/pustular skin lesions that usually occur on the feet) or balanitis circinata (moist, well-demarcated erosions with raised borders involving the penis). The syndrome is thought to be immunologically mediated and appears to be initiated by a number of infectious processes. Chlamydial urethritis appears to be a frequent precipitating factor. Ocular manifestations during Reiter's syndrome include the classic conjunctivitis, which is usually nonfollicular. Keratitis, iridocyclitis, corneal ulcerations, hypopyon, intraocular hemorrhages, posterior uveitis, and optic neuritis may also occur. Diagnosis is usually one of clinical recognition. Many clinicians

would evaluate for chlamydial involvement of the genitourinary system. If there is evidence of a sexually transmitted disease, sexual partners should also be evaluated and treated. Treatment of individuals with Reiter's syndrome involves the use of nonsteroidal anti-inflammatory agents for the arthritis. Systemic steroids are neither required nor helpful. Topical steroids may be employed in the treatment of anterior uveitis.

## Mycobacteria

### Leprosy

Ocular involvement in leprosy, caused by *Mycobacterium leprae* (see Chapter 38), is common; and, worldwide, leprosy is a leading infectious cause of visual loss.<sup>111,112</sup> Between 30% and 80% of patients with leprosy have ocular involvement.<sup>113</sup> Between 1% and 30% of patients with leprosy have an optimal visual acuity of less than 20/200, and 250,000 patients with leprosy have an optimal visual acuity of less than 20/400.<sup>114</sup>

Ocular involvement in leprosy can be due to direct mycobacterial involvement of the eye or to secondary immunologic or inflammatory manifestations. The eye may be involved during all forms of leprosy, but ocular involvement occurs most frequently during lepromatous leprosy (Fig. 129-16).<sup>115</sup> *M. leprae* prefers the cool temperatures of the anterior chamber of the eye, and ocular disease is usually anterior in nature. The eye can act as a chronic nidus of inflammation and infection. Involvement of the Vth and VIIth cranial nerves during type I lepra reactions can lead to corneal anesthesia and lagophthalmos (the inability to fully close the eyelids). Such involvement can predispose affected persons to corneal ulcerations, suppurative keratitis, corneal perforation, corneal scarring, and blindness. Staphyloma, a marked bulging of the anterior eye through a weakened corneal wall, may result (Fig. 129-17).

Persons with lepromatous leprosy may also experience erythema nodosum leprosum (type II reactions).<sup>116</sup> This form of the disease appears to be immune complex-mediated and

**FIGURE 129-16** Ocular involvement in lepromatous leprosy. Interstitial keratitis is shown by the white appearance of the margin of the cornea. Episcleritis is shown by the dilated episcleral vessels. There is chronic iritis with constriction of the pupil. Note also the loss of eyelashes. (From Sandford-Smith J: Eye Diseases in Hot Climates, 2nd ed. Oxford, Wright Publishers, Butterworth Heinemann, 1990, plate 22f.)

**FIGURE 129-17** Staphyloma secondary to marked weakening of the cornea and sclera. The damage is irreversible. (From Sandford-Smith J: Eye Diseases in Hot Climates, 2nd ed. Oxford, Wright Publishers, Butterworth Heinemann, 1990, plate 9.)

may manifest as a serum sickness-type reaction with fever, myalgias, diffuse subcutaneous nodule formation, and arthritis. Iridocyclitis and episcleritis can occur. The iridocyclitis can become chronic and can lead to iris atrophy, persistent myosis, and posterior synechiae.<sup>117</sup>

Adnexal ocular involvement during leprosy is common. Madarosis is the term used to describe leprosy-associated loss of eyelids and eyelashes (the lateral third of the eyelids is most commonly lost). Madarosis is most common in multibacillary leprosy. Lagophthalmos may be due to either type I reactions in paucibacillary disease or to chronic nerve infiltration and inflammation in multibacillary disease. Lagophthalmos may be associated with paralytic ectropion of the lower eyelid.<sup>115</sup> Multibacillary disease may be associated with a marked thickening of the eyelids and can lead to excessive folds of skin (blepharochalasis) and apparent ptosis.

Lepromatous forms of leprosy may be associated with limbic lepromas (focal, nodular mycobacterial lesions). Corneal sensation can be decreased or absent in both tuberculoid and lepromatous forms of leprosy: the former from acute reversal reactions involving the Vth cranial nerve, the latter from direct mycobacterial invasion and chronic low-grade inflammation of corneal nerve fibers. Loss of corneal sensation may precede any other ocular manifestation of leprosy.<sup>118</sup> Beading of corneal nerves, punctate keratitis, interstitial keratitis, and pannus formation may occur. Giant lepromas have been reported. Involvement of the lacrimal gland can lead to dacryoadenitis and keratoconjunctivitis sicca. Nasal collapse in multibacillary disease can lead to obstruction of the nasal lacrimal duct with resulting epiphora (excessive tearing).<sup>115</sup>

Acute or chronic iridocyclitis can occur in multibacillary disease. Iris pearls represent iris edge leproma that may be miliary or nodular. Atrophy of the dilatory muscle eventually leads to nonreactive pinpoint pupils and posterior synechiae. Intraocular pressure is often lowered during leprosy. Cataract formation may occur in patients with leprosy.<sup>114</sup> It is controversial whether chronic iridocyclitis predisposes to their formation.<sup>114</sup> Posterior ocular involvement during leprosy is infrequent but has been reported. Lepromatous choroiditis, retinal pearls, and optic neuritis have all been reported.

Diagnosis of leprosy rests on clinical recognition and involves demonstration of acid-fast bacilli in skin smears or skin/nerve biopsies. An ocular manifestation can be the

presenting feature of leprosy. Treatment of leprosy requires multidrug treatment involving dapsone, rifampin, and clofazimine. Specific ocular therapy is tailored to the given clinical manifestation. Type 1 reactions of less than 6 months' duration (including involvement of cranial nerves such as V and VII) indicate the need for immediate institution of systemic steroids. High-dose clofazimine may also be employed. Erythema nodosum leprosum reactions (with associated iridocyclitis) can be treated with systemic steroids, clofazimine, and thalidomide (contraindicated in women of childbearing age). Iridocyclitis, episcleritis, and scleritis can be treated with topical steroids.<sup>115</sup> Cycloplegics should be employed in acute iritis. Mydriatics should be employed in chronic iritis.<sup>115</sup> Chronic ocular manifestations such as lagophthalmos and ectropion may require surgical management, including tarsorrhaphy (suturing of the lateral eyelids together to protect the exposed cornea) and lid suspension.<sup>119</sup> Recognition of ocular involvement, corneal anesthesia, and lagophthalmos should prompt measures to prevent exposure keratitis and progressive ocular disease. Education, eye patches, protective glasses, repeated conscious blinking, antibiotic eye drops, and surgery should all be considered.<sup>115</sup>

### Tuberculosis

Ocular involvement occurs in less than 1% of persons with tuberculosis, caused by *Mycobacterium tuberculosis* (see Chapter 36).<sup>120</sup> Ocular structures can be involved during pulmonary tuberculosis, during systemic extrapulmonary tuberculosis, or as isolated ocular involvement.<sup>120</sup> The choroid is most frequently involved during ocular tuberculosis, perhaps because of its tremendous vascularity and numerous reticuloendothelial cells. The most common manifestation of ocular tuberculosis is multifocal choroiditis (Fig. 129-18). Involvement may also manifest as choroidal tuberculomas (Fig. 129-19), iritis, or iridocyclitis.<sup>121</sup> Involvement of the ciliary body can result in secondary glaucoma.<sup>121</sup> Choroidal tuberculomas can present as small miliary nodules or, more rarely, as large solitary masses (see Fig. 129-18). Choroidal tuberculomas represent hematogenous dissemination, and

**FIGURE 129-18** Multifocal tuberculous chorioretinitis. Note scattered lesions. (From Barondes MJ, Sponsel WE, Stevens TS, et al: Tuberculous chorioretinitis diagnosed by chorioretinal endiobiopsy. *Am J Ophthalmol* 112:460, 1991.)

**FIGURE 129-19** Choroidal tuberculoma. Gross section of the left globe. (From Lyon CE, Grimsen BS, Peiffer RL Jr, et al: Clinicopathological correlation of a solitary choroidal tuberculoma. *Ophthalmology* 92:847, 1985.)

miliary choroidal tuberculomas are often found with miliary tuberculosis. Serpiginous choroiditis and choroidal hemorrhages may occur.<sup>122</sup> When the eye itself is the site of direct infection of *M. tuberculosis*, disease is most often limited to conjunctival or corneal structures. Conjunctival involvement may be ulcerative, granulomatous, or miliary.<sup>121</sup> Preauricular adenopathy is common, and involvement is usually unilateral. Tuberculous eyelid abscesses can occur from direct deposition or from contiguous spread from sinus structures.<sup>121</sup> Phlyctenular keratoconjunctivitis can occur (Plate 129-4). A phlyctenula first appears as a raised nodule with surrounding hyperemia that becomes necrotic and then sloughs. It is thought to be an immune response to microbial proteins and is associated with a number of infectious processes, including tuberculosis.<sup>121</sup> Involvement is usually at or near the limbus. Infection with *M. tuberculosis* can also result in interstitial keratitis and corneal ulceration. Involvement of the retina is rare and most frequently associated with choroidal involvement.<sup>121</sup> Retinal vasculitis may occur. Mild vitritis has also been reported. Tuberculosis may be associated with the development of Eales' disease, an inflammatory vasculitis that predominantly affects the peripheral retina of adults. Its classic description is of a syndrome of retinal perivasculitis, peripheral retinal nonperfusion, and neovascularization. Retinal and vitreal hemorrhages can occur. The disorder has frequently been reported in South Asia.<sup>123</sup> Many causes have been postulated, including a hypersensitive reaction to the microbial products of *M. tuberculosis*.<sup>121,123</sup> Orbital tuberculosis can result from hematogenous dissemination or contiguous spread, is often unilateral, may present as proptosis, and may be associated with the formation of fistulae. Panophthalmitis may also occur.

Diagnosis of isolated ocular tubercular disease can be problematic.<sup>121</sup> Skin testing, history of exposure to tuberculosis, and chest radiography can all assist in diagnosis; however, the diagnosis is usually one of clinical recognition. The presence of choroidal tuberculomas is often helpful. Persons with AIDS and tuberculosis may have positive blood cultures.<sup>124</sup> Ocular tuberculosis responds well to standard systemic multidrug

chemotherapeutic regimens. Ethambutol therapy itself, however, may cause optic neuritis.<sup>121</sup>

### Atypical Mycobacteria

Atypical mycobacteria are rare causes of ocular infection, although atypical mycobacterial keratitis following LASIK (laser assisted in situ keratomileusis) surgery is being increasingly recognized (see Chapter 36). *M. fortuitum* and *M. chelonae* are the atypical mycobacteria that most frequently affect the eye.<sup>125</sup> Keratitis, corneal ulceration, orbital granulomas, scleral abscesses, iritis, and endophthalmitis have been reported. Such involvement is usually associated with trauma or surgery or occurs in persons who wear contact lenses. Such involvement is thought to be secondary to the direct deposition of organisms. *M. gordonae*, *M. marinum*, and *M. flavescens* have more rarely been associated with keratitis. *M. avium-intracellulare*/*M. avium* complex (MAI/MAC) has been associated with corneal ulcerations, preseptal cellulitis, endophthalmitis, and choroiditis (the latter being associated with coinfection with HIV).<sup>125</sup>

Diagnosis of atypical mycobacterial infection of the eye is based on demonstration of organisms by acid-fast staining and culture. Persons with HIV disease and disseminated MAI/MAC infection may have positive blood cultures. Atypical mycobacteria are often resistant to the chemotherapeutic agents that are used in the treatment of tuberculosis. Clarithromycin may be effective. Topical therapy with amikacin and a second or third topical agent such as a fourth-generation fluoroquinolone antibiotic (such as moxifloxacin or gatifloxacin) or clarithromycin (depending on sensitivity assays of the specific organism) is usually effective for keratitis.<sup>126</sup> Surgical extirpation is usually required.<sup>126</sup> Disseminated MAI/MAC disease should be treated with systemic therapy.

### Spirochetes

#### Treponematoses

**Syphilis.** Syphilis is caused by *Treponema pallidum* (see Chapter 44). The eye can be involved during all stages of congenital or acquired syphilis. During primary acquired syphilis, chancres of the eyelid, conjunctiva, and lacrimal gland have been reported. During the rash of secondary syphilis, conjunctivitis and blepharitis can occur. Approximately 10% of persons with secondary syphilis have ocular involvement. Madarosis (loss of eyelashes and eyebrows) has been reported. Keratitis, iritis, iris hyperemia (roseolae), iris nodules, episcleritis, and scleritis can also occur. Anterior uveitis is the most common ocular finding during secondary syphilis. Keratitis may be unilateral. Chorioretinitis (that may be placoid), peripapillary neuroretinitis, pigmentary retinitis, retinal vasculitis, and vitritis may also occur. Retinal detachment and a “salt-and-pepper” retinopathy can result. During tertiary syphilis, the eyelid, lacrimal glands, and deep ocular structures can be involved with destructive gummatous lesions. Orbital bones may be involved with periostitis that can be bilateral. Chronic interstitial keratitis is not infrequent (Fig. 129-20). The most common ocular manifestations of syphilis are uveitis and optic neuritis, although iritis, episcleritis, scleritis, chorioretinitis, papillary neuroretinitis, vitritis, and retinal vasculitis can occur. Occlusive retinal vascular disease, neovascularization,

**FIGURE 129-20** Central stromal scarring and ghost vessel formation secondary to late latent syphilitic interstitial keratitis. (From Brooks AMV, Weiner JM, Robertson IF: Interstitial keratitis in untreated latent [late] syphilis. *Aust NZ J Ophthalmol* 14:128, 1986.)

aneurysm formation, retinal detachments, and pigmentary retinopathy can also occur.

Neurosyphilis can occur during any stage of clinical disease. Meningovascular syphilis can be associated with neurophthalmic complications. Nerve palsies can result in ocular dysmotilities. The classic Argyll Robertson pupil may be visible in meningovascular syphilis. It manifests as a small, irregular pupil that reacts normally to accommodation but not to light. Papilledema can also occur. Neurophthalmic findings are possible with parenchymous neurosyphilis, but they are rare. Argyll Robertson pupil and optic atrophy can be seen in tabes dorsalis.

Ocular involvement during congenital syphilis may be mild or even asymptomatic. Clinically evident involvement during the first few months of life can include conjunctivitis, iridocyclitis, uveitis, optic neuritis, salt-and-pepper chorioretinitis, extraocular paresis, and neurophthalmic manifestations. Disease often becomes quiescent, with only pigmentary retinopathy being subsequently evident. The disease can reactivate, however, and an affected patient can present with chronic interstitial keratitis as an adolescent or as an adult. Such involvement is usually bilateral and is most often misdiagnosed. Chronic inflammation can lead to scarring, neovascularization, and residual “ghost vessel” formation. Hutchinson’s triad includes malformed Hutchinson’s teeth, deafness (from VIIIth nerve involvement during neurosyphilis), and interstitial keratitis. Iritis or keratouveitis may occur and can result in secondary glaucoma. Chronic retinitis and pigmentary retinopathy may be evident.

Ocular syphilitic involvement in neurosyphilis appears to be common during concurrent infection with HIV.<sup>127</sup> Involvement is possible even in patients previously treated for syphilis.<sup>127</sup> Conjunctivitis, iridocyclitis, uveitis, retinitis, neuroretinitis (Fig. 129-21), vitritis, papillitis, optic perineuritis (Fig. 129-22), and retrobulbar neuritis have all been reported.<sup>127</sup> Standard therapeutic regimens for the treatment of syphilis assume an intact immunologic system. Eradication of *T. pallidum* from ocular structures and from the central nervous system in immunodeficient persons, such as those coinfecting with HIV, requires higher doses and longer duration of penicillin therapy.<sup>127</sup>

**FIGURE 129-21** A large wedge-shaped area of syphilitic neuroretinitis with small cotton wool spots. (From McLeish WM, Pulido JS, Holland S, et al: The ocular manifestations of syphilis in the human immunodeficiency virus type 1–infected host. *Ophthalmology* 97:198, 1990.)

Diagnosis is usually based on clinical recognition and serologic examination. A lumbar puncture should be performed to evaluate for concomitant neurosyphilis. Independent of the evaluation of the central nervous system, all persons with ophthalmic manifestations of syphilis should be treated with a 10- to 14- day course of intravenous high-dose penicillin therapy. Certain immunocompetent persons with an isolated primary chancre of the eyelid or periorbital area could be treated with short, low-level therapy. Follow-up serologic analysis should be performed to monitor post-therapy resolution of disease. Follow-up analysis of cerebrospinal fluid should be performed in patients with neurosyphilitic involvement. Topical steroids, mydriatics, and cycloplegics may also be employed for anterior syphilitic inflammatory ocular disease, including keratitis and uveitis. Sexual partners

**FIGURE 129-22** Syphilitic optic perineuritis with disk swelling. (From McLeish WM, Pulido JS, Holland S, et al: The ocular manifestations of syphilis in the human immunodeficiency virus type 1–infected host. *Ophthalmology* 97:198, 1990.)

of affected persons need to be appropriately evaluated and treated.

### Endemic Treponematoses

**Nonvenereal Endemic Syphilis: Bejel.** Syphilis (bejel) is a nonvenereal treponematoses caused by a variant of *T. pallidum* that is morphologically and serologically indistinguishable from that which causes venereal syphilis (see Chapter 44). Endemic syphilis is rarely, if ever, sexually transmitted, has not been associated with congenital infection, and is rarely, if ever, associated with late cardiac or neurologic manifestations. A number of ocular manifestations, including anterior uveitis, choroiditis, and chorioretinitis have been postulated to be a late manifestation of bejel.<sup>128</sup> Diagnosis is one of clinical recognition in an appropriate demographic setting. Serologic assays cannot distinguish between venereal and nonvenereal syphilis, so it is clinically impossible to firmly ascribe isolated ocular disease to venereal and nonvenereal syphilis. The treatment of nonvenereal syphilis is penicillin. Active uveitis resolves on penicillin therapy alone.<sup>128</sup>

**Yaws.** Yaws (pian, framboesia) is caused by *Treponema pertenue*. The infection is found in warm tropical areas throughout the world, is spread by bodily contact, and has distinct early, latent, and late-stage manifestations (see Chapter 44). Yaws has been associated with neurophthalmic abnormalities (including Argyll Robertson–type pupillary responses), sheathing of retinal vessels, perivascular pigmentation, and optic atrophy. Spirochetes have been identified in the anterior chamber, and iritis has been reported. Acute skin lesions can involve the eyelid and may result in catarrhal conjunctivitis. Scarred/healed skin lesions of the face may result in ectropion. Massive destruction of the nasal mucosa can result in saddle-nose, and central facial necrosis (yaws gangosa) can result in destruction of the eye and orbit. Serologic assays cannot distinguish yaws from syphilis.

**Pinta.** Pinta (mal de pinto) is caused by *Treponema carateum* (see Chapter 44). No ocular abnormality has definitely been associated with pinta except for scarring skin lesions that have involved the eyelids.<sup>129</sup>

### Leptospirosis

Leptospirosis can be caused by a number of *Leptospira* species (see Chapter 46). During the acute leptospiremic phase, a retro-orbital headache can occur. Conjunctival suffusion and photosensitivity are common. During the immune phase, meningitis can occur that may be associated with cranial nerve paresis and optic neuritis. If the severe form of leptospirosis, Weil's disease, develops, scleral jaundice and conjunctival and retinal hemorrhages can occur. Uveitis is the most frequent ocular manifestation after conjunctival suffusion. The uveitis may present from 10 days to many months after the initial infection.<sup>130</sup> The initial infection may even have been clinically asymptomatic. Uveitis, often acute and bilateral, usually presents as anterior uveitis and iridocyclitis. Anterior chamber involvement, hypopyon, elevated intraocular pressure, and synechiae can occur. Posterior uveitis, vitreal clouding, retinal exudates, and retinal hemorrhages may also occur. Diagnosis involves serologic assay for antibodies. Treatment of leptospirosis involves systemic

penicillin, tetracycline, or doxycycline. Leptospiral anterior uveitis may be treated with topical steroids and mydriatics. Systemic steroids may rarely be required.

### Relapsing Fever

Epidemic relapsing fever is caused by louse-borne *Borrelia recurrentis*; endemic relapsing fever is caused by tick-borne *B. duttoni* (see Chapter 45). Ocular manifestations during acute relapsing fever include photophobia, eye pain, and conjunctivitis. During severe episodes of relapsing fever, bleeding diathesis can occur, and conjunctivitis and conjunctival and intraocular hemorrhages can result. Meningoencephalitis and cranial neuritis can occur. Involvement of the VIth and VIIth cranial nerves can result in disorders of ocular motility and ptosis. Optic neuritis can occur. Uveitis may be the most frequent ocular manifestation associated with relapsing fever and can occur after several relapses of the disorder. Iridocyclitis is most common, and posterior synechial formation can result. Posterior uveitis, vitritis, vitreal exudates, and retinal venous occlusion have all been reported. The febrile episodes can precipitate reactivation of latent herpes simplex keratitis. Diagnosis usually involves demonstrating spirochetes in peripheral blood during acute illness. Relapsing fever-associated uveitis may occur late in the disease course, and demonstration of *Borrelia* organisms may then be problematic. Acridine-orange fluorescent stain and analysis of bone marrow samples may be helpful. Serologic antibody and antigenic assays and molecular diagnostic techniques are available.

### Rickettsia

Louse-borne epidemic typhus is caused by *Rickettsia prowazeki*. Flea-borne endemic typhus is caused by *R. mooseri*. The clinical manifestations of endemic typhus are similar to those of epidemic typhus but are usually less severe (see Chapter 51). Ocular manifestations are predominantly visible during epidemic typhus. During acute epidemic typhus, conjunctival suffusion may occur and can predate the appearance of the body rash. The rash itself may be associated with small, oval, pink-purple, conjunctival lesions. Persons with typhus may appear to have a glassy-eyed “drugged look.” Keratoconjunctivitis has been reported, and hemorrhagic manifestations can lead to conjunctival and intraocular hemorrhages. The vascular damage induced by rickettsial infection can lead to vascular thrombosis, retinal vasculitis, retinal hemorrhages, and possibly uveitis.

Tick-borne rickettsial spotted fevers can be caused by many *Rickettsia* species, including *R. rickettsii* (the cause of Rocky Mountain spotted fever), *R. conorii* (the cause of boutonneuse fever), and *R. africae* (the cause of African tick fever; see Chapter 50). Mite-borne scrub typhus is caused by *R. tsutsugamushi* (see Chapter 52). An eschar may be evident at the site of the tick or mite bite in boutonneuse fever/African tick fever or scrub typhus, respectively. Eschars can involve the lid and periocular structures. Conjunctival suffusion and photophobia may occur in acute cases of rickettsial spotted fevers or in scrub typhus. Direct ocular inoculation of infectious blood from crushed ticks can result in conjunctivitis, corneal ulceration, and preauricular adenopathy (Parinaud’s ocular glandular syndrome).<sup>131,132</sup> Bilateral anterior uveitis,

papilledema, retinal vein engorgement, retinal hemorrhage, retinal vein occlusion, papillitis, and optic neuritis can occur.<sup>133</sup> Meningoencephalitis can result in cranial nerve dysfunction and in ocular palsies. Diagnosis involves specific serologic assays and molecular techniques.

### Mycoplasma

#### *Mycoplasma pneumoniae*

*Mycoplasma pneumoniae* is associated with the development of Stevens–Johnson syndrome/erythema multiforme major (SJS/EMM). With SJS, vesicles and bullae can involve mucocutaneous surfaces, including conjunctivae. Conjunctival involvement is present in 50% to 80% of patients with SJS/EMM. Catarrhal conjunctivitis, pseudomembranous conjunctivitis, and membranous conjunctivitis can occur. Anterior uveitis has been reported. The residual scarring can lead to keratitis sicca, lid retraction, corneal pannus formation, corneal opacifications, corneal ulcerations, and corneal perforations. Trichiasis and lagophthalmos can occur. Epiphora can result from scarring of lacrimal puncta and canaliculi. Late ocular complications are directly related to the severity of the primary SJS.<sup>134</sup> *M. pneumoniae*-associated SJS has a male predominance and tends to occur in younger patients.

Diagnosis of *M. pneumoniae* infection is usually based on clinical recognition. Cold agglutinins may be present. *M. pneumoniae*-specific antibody serologic assays, antigenic assays, and molecular techniques are available. Treatment involves tetracycline, macrolides, and certain fluoroquinolone antibiotics. The role of steroids in the treatment of SJS/EMM is controversial. Secondary complications may require surgical intervention.<sup>135</sup> Ocular lubrication and protection of the cornea and the visual axis should be primary goals.

#### *Mycoplasma hominis/Ureaplasma urealyticum*

*M. hominis* may be present in genital secretions and may be associated with mild neonatal conjunctivitis. *Ureaplasma urealyticum* may be associated with the development of conjunctivitis as part of the presentation of Reiter’s syndrome.

### Actinomyces

#### Actinomycosis

Actinomycosis can be caused by a number of species of *Actinomyces*. The organisms are worldwide in distribution and are part of the mouth flora. Ocular manifestations are usually due to *Actinomyces israelii* and is due to direct deposition of organisms or contiguous spread.<sup>136</sup> Actinomycosis can cause canaliculitis and can involve the lacrimal sac. The chronic inflammation can lead to obstruction of tear drainage, epiphora, and chronic conjunctivitis. Lacrimal sac involvement can lead to laminated concretions that obstruct normal tear drainage.

Orocervicofacial actinomycosis is characterized by an expansile cold abscess that begins at the mucosal surface of the oropharynx and does not respect anatomic borders. Sinus tract formation and fistula formation/drainage are common. Infection can involve sinuses, and direct extension into orbital

tissues can occur. *Actinomyces* species may also be introduced into ocular structures during ocular surgery or through trauma.<sup>137</sup> Diagnosis of actinomycotic infection is confirmed by culture. Examination of tissue samples or secreted granules can disclose the characteristic stellate radiations of the organism. Isolated canaliculitis may be treated with local antibiotics. Expression of lacrimal duct concretions should be attempted in order to reestablish normal tear flow. Curettage and irrigation may be required. Prolonged high-dose penicillin therapy is required for deep involvement. Tetracycline and erythromycin may also be effective. Percutaneous drainage of an abscess or surgical intervention may be required.

### Nocardia

*Nocardia* species are soil organisms that are worldwide in distribution. Nocardial ocular infections are rare, but they do occur. Ocular involvement in immunocompetent persons is usually related to trauma, introduction of foreign bodies, or surgical manipulation. Involvement in immunocompromised persons is usually secondary to hematogenous dissemination (usually from a pulmonary focus). Dacrocystitis or canaliculitis with concretions (similar to that associated with actinomycosis) can occur. Preseptal cellulitis, catarrhal conjunctivitis, keratitis, or corneal ulcerations may all occur after contaminating inoculation.<sup>138</sup> Regional lymphadenopathy may be present.<sup>138</sup> Nocardial uveitis, iritis, necrotizing chorioretinitis, and endophthalmitis can occur in immunocompromised persons.<sup>139</sup> Retinal detachment and endophthalmitis can occur. Diagnosis is usually based on culture results. Treatment should be systemic for intraocular disease and usually includes a sulfonamide, often administered as trimethoprim–sulfamethoxazole. Amikacin may be added.<sup>139</sup> Prolonged therapy may be required. Nocardial canaliculitis may be treated with topical sulfacetamide drops. Nocardial keratitis in immunocompetent persons may be treated with local application of trimethoprim–sulfamethoxazole or amikacin.

### Whipple's Disease

Whipple's disease is caused by *Tropheryma whippelii*, a gram-positive, non-acid fast, periodic acid-Schiff (PAS)–positive bacillus with a characteristic trilamellar plasma membrane surrounded by a cell wall. It is related to *Actinomyces* and is probably fairly ubiquitous in soil. The organism can be identified in the saliva of 10% to 30% of healthy individuals. In certain individuals (usually Caucasian males), the organism is able to cause deep systemic infection. In these individuals, there is a marked absence of any immune or cytotoxic response and organisms replicate freely within foamy macrophages. The classic manifestations of Whipple's disease include a large joint arthritis, diarrhea, weight loss, and abdominal pain. Rash and neurological and ocular manifestation are common. Ocular manifestation includes uveitis and ocular movement disorder; ocular movement manifestations pathogenomic for Whipple's disease include oculomasticatory myorhythmia (continuous rhythmic movements of eye convergence with concurrent contractors of masticatory muscles) and oculo-facial-skeletal myorhythmia.<sup>140–142</sup> These abnormalities are usually accompanied by supranuclear vertical gaze palsy. Posterior uveitis may be present.<sup>143</sup> Diagnosis is usually based

on identification of organisms on pathology specimens or using molecular techniques. Treatment should be systemic and prolonged and usually involves trimethoprim–sulfamethoxazole or penicillin. Retinal Jarisch–Herxheimer reactions have been reported.<sup>144</sup> Relapses are common.

### Brucellosis

Brucellosis in humans may be caused by *Brucella melitensis*, *B. suis*, *B. abortus*, or *B. canis* (see Chapter 41). Ocular manifestations during the acute/early stage of infection include endophthalmitis and optic neuritis. There may be marked pain on eye movement. Involvement of the meninges during *Brucella* meningoencephalitis can result in ocular palsies and in papilledema. Ocular manifestations during the more chronic phase of infection may include uveitis, which may be granulomatous, episcleritis, and nummular keratitis.<sup>145</sup> Isolated iridocyclitis or choroiditis may occur.<sup>145</sup> Uveitis may be the only apparent manifestation of brucellosis and may occur after appropriate antibrucellosis therapy has been employed.<sup>145</sup> Less common manifestations may include dacryoadenitis, conjunctivitis, corneal ulceration, retinal detachment, papillitis, and retrobulbar optic neuritis.<sup>146</sup> Optic atrophy may result.

Diagnosis is usually based on a serologic assay. Direct culture of infected material may be helpful during the early stage of infection. Therapy of brucellosis involves prolonged administration of a combination of antimicrobial agents. Doxycycline and rifampin or trimethoprim–sulfamethoxazole are often employed. Streptomycin or other aminoglycosides are often coadministered for severe infections. Ocular manifestations during early disease usually respond best to systemic antibrucellosis therapy. Optic neuritis has been treated with systemic steroids and systemic antibrucellosis therapy. Late manifestations of disease may in part be immunologically mediated. Anterior uveitis may be treated with topical steroids, mydriatics, and systemic antimicrobial agents.<sup>145</sup>

### Tularemia

Tularemia is caused by *Francisella tularensis*. Ocular manifestations usually result from deposition of the organism either through direct inoculation of infectious material on or around ocular structures or through aerolization. The disease may be bilateral. Deposition on the conjunctivae may result in an ulceronodular conjunctivitis that is usually painful.<sup>147,148</sup> Chemosis, injection, and excessive lacrimation may be present. Painful, local lymphadenopathy may be prominent. Tularemia is a leading cause of Parinaud's oculoglandular syndrome.<sup>147</sup> Nodal suppuration, corneal ulceration, and dacryocystitis can occur.<sup>148</sup> Although the organism may be cultured, the diagnosis is usually confirmed with antibody-based serologic assays. Streptomycin is the treatment of choice. Gentamicin may also be effective.

### Bartonella Infections

#### Trench Fever

A number of *Bartonella* species can cause disease in humans (see Chapter 40). *Bartonella quintana* is the cause of trench fever. Ocular manifestations occur only as part of the systemic illness. The headache of trench fever is often

localized at the front of the head and behind the eyes. Conjunctival injection and congestion can occur. Diagnosis is usually based on antibody-based serologic assay. Culture and molecular analyses are also available.

### Bacillary Angiomatosis

*B. quintana* and *B. henselae* can cause bacillary angiomatosis (see Chapter 40). The vascular proliferative lesions of bacillary angiomatosis may involve the conjunctiva, eyelid, and anterior orbit.<sup>149</sup> Lesions may appear superficially similar to those of Kaposi's sarcoma. Diagnosis is usually based on histologic examination of biopsy samples. Treatment usually involves erythromycin or doxycycline, often with an aminoglycoside.

### Cat-Scratch Disease

*B. henselae* is also a cause of cat-scratch disease (see Chapter 40). Ocular manifestations due to *Bartonella* species infections are most frequently associated with cat-scratch disease. Parinaud's oculoglandular syndrome with unilateral conjunctivitis and adjacent preauricular lymphadenopathy is the most common ocular manifestation of bartonellosis (Fig. 129-23). Conjunctival involvement may be granulomatous. Cat-scratch disease may also be associated with encephalopathy that may result in cranial nerve dysfunction and in ocular palsies or dysmotilities. Optic neuritis and stellate macular retinitis may also occur (Fig. 129-24).<sup>150</sup> The latter entity is called Leber's stellate neuroretinitis and may present as a painless, unilateral (rarely bilateral) loss of vision, with a central scotoma, optic disk swelling, and macular star formation. Inflammation and occlusion of retinal vessels may occur.<sup>151</sup> Disciform keratitis, orbital masses, and retinal detachments have also been reported. The retinal star is related to exudative leakage of optic nerve capillaries. Diagnosis of *B. henselae* infection during cat-scratch disease is usually based on serologic assay. Culture and molecular assays may also be employed. Treatment is of uncertain benefit, but, if administered, usually involves clarithromycin, azithromycin,

**FIGURE 129-23** Parinaud's oculoglandular syndrome secondary to *Bartonella* (*Rochalimaea*) *henselae* infection. Note the oval, granulomatous lesion of the eyelid conjunctiva and the ipsilateral preauricular adenopathy delineated by the ruler. (From Bass JW, Vincent JM, Person DA: The expanding spectrum of *Bartonella* infection: II. Cat scratch disease. *Pediatr Infect Dis J* 16:170, 1997.)

**FIGURE 129-24** *Bartonella* infection–associated Leber's stellate macula retinitis. (From Bass JW, Vincent JM, Person DA: The expanding spectrum of *Bartonella* infection: II. Cat scratch disease. *Pediatr Infect Dis J* 16:171, 1997.)

erythromycin, tetracycline, rifampin, sulfonamides, or quinolones. Systemic steroids are also sometimes administered to individuals with cat-scratch disease–associated optic neuritis or neuroretinitis.<sup>152</sup>

### Carrion's Disease

*B. bacilliformis* is the cause of Carrion's disease, which during its early stage may manifest as Oroya fever and during its late stage may manifest as verruca peruana (see Chapter 40). Verruca peruana is associated with the formation of vascular proliferative nodular lesions, which are similar to those observed in bacillary angiomatosis. The skin is the most frequently involved site, but mucous membranes (including the conjunctiva) may also be affected. Diagnosis during Oroya fever is usually based on culture or microscopic examination of peripheral blood for erythrocyte-adherent bacteria. Diagnosis of verruca peruana is usually based on histologic examination. Treatment may include chloramphenicol, penicillin, tetracycline, fluoroquinolones, or macrolides.

### Q Fever

Q fever is caused by *Coxiella burnetii* (see Chapter 54). Ocular manifestations are rare; however, cranial nerve palsies and optic neuritis have been reported.<sup>153</sup> Diagnosis usually involves serologic assay, although culture analysis may be employed. Optic neuritis may be treated with antibiotics and systemic steroids. Even with appropriate therapy, optic atrophy and residual visual loss are frequent.<sup>153</sup>

### Anthrax

Anthrax is caused by *Bacillus anthracis* (see Chapter 39). The eye and periocular structures may be involved by the eschar and edema of cutaneous anthrax.<sup>154</sup> Preseptal cellulitis can occur.<sup>155</sup> Extensive eyelid scarring can lead to severe ectropion. Diagnosis is usually based on clinical appearance, microscopic examination, or culture. Molecular and antigen assays are available.

## Diphtheria

Diphtheria is caused by *Corynebacterium diphtheriae* (see Chapter 35). Ocular diphtheria may occur after or concurrently with nasopharyngeal diphtheria, oropharyngeal diphtheria, or cutaneous diphtheria.<sup>156</sup> Ocular diphtheria can also occur independently of other diphtheric manifestations.<sup>157</sup> Ocular diphtheria usually presents as membranous or pseudomembranous conjunctivitis, nonspecific purulent conjunctivitis, or a corneal process. Affected eyelids and conjunctivae are “hardened,” tender, and erythematous. Pain and preauricular adenopathy may be pronounced, and discharge is initially minimal. Conjunctival membranes or pseudomembranes may then appear. Such membranes represent necrotic material/cellular debris and are leather-like and pale gray in appearance. Subepithelial petechiae may be present.<sup>156</sup> Vascular necrosis is common. If the adherent membrane is removed, punctate hemorrhages appear. The membrane eventually sloughs with extensive exudation. Granulation tissue then appears. Healing can lead to extensive scar formation, with such secondary ocular sequelae as entropion, trichiasis, and xerosis.<sup>157</sup> The cornea may also be involved in acute disease. Corneal erosions and a punctate keratitis may occur.<sup>156</sup> Corneal ulceration can lead to total destruction of the cornea within hours of presentation.<sup>157</sup> Diphtheria toxin that is systemically absorbed from any site (e.g., nasopharyngeal, oropharyngeal) can lead to demyelinating neuritis. Cranial nerve paralysis can then occur and can result in disorders of ocular motility and ciliary function.

Diagnosis is usually one of clinical recognition and culture analysis. If the diagnosis of diphtheria is considered, treatment with systemically administered antitoxin should begin immediately, prior to culture confirmation. Prevention or minimization of such catastrophic complications as carditis and neuritis are associated with early administration of systemic antitoxin. It should be recalled, however, that the presence of membranous or pseudomembranous conjunctivitis is not pathognomonic for ocular diphtheria (see Box 129-1). Such membranes may be seen with conjunctival infections due to pneumococci, *Streptococcus* species, *Neisseria* species, certain enteroviruses, and adenovirus 8.<sup>156</sup> A Gram stain may be helpful; however, large gram-positive rods may be commensal conjunctival organisms (e.g., *Corynebacterium xerosis*).<sup>156</sup> Treatment of diphtheria is twofold. Primary therapy involves the administration of equine diphtheria antitoxin. Allergic testing should precede systemic administration because 5% to 10% of persons are allergic to equine antiserum. Antibiotics should also be administered and usually involve the use of penicillin or erythromycin. Topical antibiotics may be used to supplement the systemic regimen. Affected persons should be placed in isolation. Long-term sequelae of ocular diphtheria (such as entropion) may require surgical intervention.

## Botulism

Botulism is caused by neurotoxins produced by *Clostridium botulinum*. Blurred vision secondary to mydriasis is often the presenting clinical feature of botulism.<sup>158</sup> Autonomic dysfunction may also manifest as paresis of accommodation and as dry eye.<sup>158</sup> Involvement of cranial nerves may result in ptosis,

diplopia, ophthalmoplegia, and nystagmus.<sup>159–162</sup> Pupillary abnormalities may be present and may persist for months.<sup>159</sup> Ocular manifestations may vary, depending on the type of botulism toxin being produced.<sup>161</sup> Diagnosis is usually based on antigenic assays for toxin, culture, and electrophysiologic studies. Therapy involves administration of equine antitoxin with preliminary skin testing. Intestinal purgatives or lavage may be employed if contaminated food is thought to be still present within the intestinal lumen. Persons with wound botulism should undergo débridement. Botulism toxin could be used as an agent of bioterrorism and the simultaneous presentation of many individuals with blurred vision should prompt consideration of intentional or inadvertent intoxication.<sup>163</sup> Systemic penicillin or metronidazole is often coadministered. Administration of antitoxin only limits or prevents additional neuronal damage. Established and developing neuronal dysfunction should be managed supportively, including the possible use of respiratory support.

## Tetanus

Tetanus is caused by the neurotoxins of *Clostridium tetani* (see Chapter 43). Ocular manifestations can occur during any manifestation of tetanus (generalized, localized, cephalic, and neonatal) but are most frequently observed during cephalic tetanus. Cephalic tetanus usually results from production of toxin from a local head or neck infection. Cephalic tetanus is associated with cranial nerve dysfunction.<sup>164,165</sup> Ocular involvement during tetanus may include ptosis, ocular palsies, ophthalmoplegia, saccadic eye movements, and supranuclear palsies.<sup>165–168</sup> Facial palsies may also occur.<sup>169</sup> Ocular structures may themselves also be directly infected by *C. tetani* organisms, usually in the setting of traumatically introduced foreign bodies.<sup>170</sup> Orbital cellulitis, corneal infection, and panophthalmitis have all been reported. Diagnosis is one of clinical recognition. Strychnine poisoning needs to be excluded. Treatment involves the use of passive immunization with human tetanus immunoglobulin. Débridement of wounds is required. Systemic metronidazole or penicillin is usually employed. The respiratory status and autonomic instability of affected persons need to be appropriately managed. Benzodiazepines and intensive supportive care are required. An effective vaccine is available. Active immunization with the vaccine should be employed even in persons who have survived clinical tetanus.

## Neisseria Species

### *Neisseria meningitidis*

*N. meningitidis* can involve the eye in a number of ways (see Chapter 25). Primary purulent conjunctivitis can occur.<sup>171</sup> The conjunctivitis is hyperacute, with production of extensive purulent discharge (Fig. 129-25).<sup>171</sup> Involvement is usually unilateral and may include subconjunctival hemorrhages.<sup>171</sup> Keratitis can occur, and corneal ulceration and endophthalmitis may result.<sup>171</sup> Ocular structures may also be involved during meningococcemia or meningococcal meningitis.<sup>37,172</sup> Conjunctival petechiae and hemorrhages, iritis, hypopyon, vitritis, endophthalmitis, panophthalmitis, and orbital cellulitis may then occur. Diagnosis rests on clinical recognition

**FIGURE 129-25** *Neisseria meningitidis* hyperacute conjunctivitis. (From Al-Mutlaq F, Byrne-Rhodes KA, Tabbara KF: *Neisseria meningitidis* conjunctivitis in children. Am J Ophthalmol 104:281, 1987.)

and culture. Gram stain of conjunctival scrapings may disclose the presence of gram-negative diplococci.<sup>171</sup> Treatment should be systemic, even in isolated conjunctival disease. Such an approach has been shown to lessen the incidence of subsequent systemic dissemination.<sup>171</sup>

#### *Neisseria gonorrhoeae*

*N. gonorrhoeae* is a more common cause of hyperacute purulent conjunctivitis (see Fig. 129-25) than is *N. meningitidis* (see Chapter 26). Keratitis, corneal ulceration/perforation, iritis, panophthalmitis, and lid abscesses can occur. Involvement is usually unilateral. Lymphadenopathy may be present. The disease not only involves sexually active persons, but also affects neonates. Gonococcal ophthalmia neonatorum usually begins between 1 and 13 (usually 2 to 5) days after birth, is often bilateral, and is often markedly purulent.<sup>102,104</sup> Corneal ulceration and perforation can occur. Corneal scarring, neovascularization, and blindness may result.<sup>173</sup> Diagnosis is based on microscopic examination of conjunctival smears and culture. Treatment should be systemic. Ceftriaxone may be employed. The mother of an affected infant, the mother's sexual partner(s), and adults with *N. gonorrhoeae*-associated conjunctivitis should be examined for the presence of additional sexually transmitted diseases and appropriately treated. Local irrigation and removal of conjunctival purulent material should be performed. Topical therapy may supplement systemic therapy. Prophylactic regimens of topical silver nitrate, tetracycline, and erythromycin should be used at the time of birth to prevent or diminish the chance of ophthalmia neonatorum.<sup>173</sup>

#### Brazilian Purpuric Fever

Brazilian purpuric fever is caused by *Haemophilus influenzae* biogroup *aegyptius* (previously known as *H. aegyptius*; see Chapter 28).<sup>174</sup> The disorder may manifest as a purpura fulminans, with high fever, abdominal pain, vomiting, vascular collapse, purpura, and necrosis.<sup>174</sup> The disorder occurs 3 to 15 days after an episode of purulent conjunctivitis caused by a specific strain/clone of *H. influenzae* biogroup *aegyptius*.

Blood cultures are often positive during the severe illness.<sup>175</sup> The disorder mimics meningococcemia. Treatment of Brazilian purpuric fever involves systemic antibiotics and supportive care. Mortality can approach 70%. The disease occurs even in persons in whom topical antibacterial agents have been employed in the therapy of purulent conjunctivitis.

#### Chancroid

Chancroid is a sexually transmitted disease caused by *Haemophilus ducreyi* (see Chapter 27). Ocular involvement is rare but has been reported, presumably secondary to ocular inoculation of contaminating secretions.<sup>104</sup> Involvement of the eyelid, conjunctiva, or both has been reported. The chancroid papule forms a shallow, painful, purulent ulcer. Conjunctivitis can occur. Marked enlargement of preauricular lymph nodes can occur. Diagnosis is usually based on clinical recognition, the presence of characteristic "schools of fish" gram-negative bacilli on Gram stain of ulcer secretions, and, rarely, culture. Treatment is systemic.

#### Cholera

Cholera is caused by *Vibrio cholerae* O1 and *V. cholerae* O139 (see Chapter 21). Ocular manifestations during cholera are directly related to the severe volume loss and osmotic/electrolyte disturbances that occur in affected persons. Severe dehydration leads to the characteristic "sunken" eyes of patients with cholera (Fig. 129-26). There is a decrease in tear production and in spontaneous blinking. Conjunctivitis and exposure keratitis with subsequent corneal ulceration may result. Fluid and osmotic shifts may result in corneal edema and can precipitate the sudden development of bilateral cataracts.

#### Typhoid

Typhoid due to *Salmonella enterica* serovar Typhi can involve ocular structures (see Chapter 17). Rose spots can involve the conjunctiva, and conjunctivitis has been reported. Involvement of the central nervous system during typhoid

**FIGURE 129-26** Woman with severe dehydration from cholera. Note the sunken and unclosed eyes.

can result in cranial nerve dysfunction, pupillary disturbances, and extraocular palsies. Severe dehydration and osmotic shifts can lead to cataract formation.

### Bacillary Dysentery

Bacillary dysentery is classically associated with shigellosis, although it may also be caused by a number of other infectious agents (see Chapters 16, 18, 19, and 20). Direct ocular deposition of *Shigella* species can result in conjunctivitis, keratitis, and corneal ulceration. Diffuse orbital inflammation of unclear etiology may occur.

The conjunctivitis associated with Reiter's syndrome may be precipitated by an episode of dysentery-type diarrhea caused by *Shigella* species, *Salmonella* species, *Campylobacter* species, and *Yersinia* species, among others. Such involvement can occur 1 to 4 weeks after resolution of the dysenteric symptoms.<sup>176</sup> Uveitis and iridocyclitis may be observed. Synechial formation may occur. Nonshigellosis dysenteric pathogens may also more rarely be associated with direct infection of ocular tissues and can result in a conjunctivitis, keratitis, Parinaud's oculoglandular syndrome, and endophthalmitis. Diagnosis is one of clinical recognition and historical questioning. Cultures are often unrevealing in cases of postdysenteric ocular disease, although they are helpful in infective ocular cases. Treatment involves systemic antibiotics for infective cases. Postdysentery immunologically mediated ocular reactions may be managed with topical steroids.<sup>176</sup>

### Melioidosis and Glanders/Farcy

Melioidosis is caused by *Burkholderia pseudomallei* (see Chapter 34). Ocular involvement may occur after direct traumatic deposition of the organism or from hematogenous dissemination. Necrotic scleral nodules and orbital abscesses may present with chemosis and exophthalmos. Chronic untreated infections may be associated with the development of a mild iritis. Intracerebral abscesses may form and can lead to papilledema. Diagnosis is usually made by culture.

Glanders is a systemic disease with a primary pulmonary component caused by *Burkholderia mallei*. Farcy is the term used to describe infection by *B. mallei* that presents predominantly with ulcerative lesions of the skin with lymphadenopathy. The disease is predominantly a disorder of equines. Infection in humans can occur from direct deposition of organisms on mucous membranes. Conjunctival deposition can result in a mucopurulent conjunctival discharge with preauricular lymphadenopathy. An ulcerative granulomatous lesion can occur, which may present as Parinaud's oculoglandular syndrome. Photophobia and lacrimation may be pronounced. Diagnosis is usually confirmed by culture.

### Bacterial Keratitis and Conjunctivitis

Bacterial keratitis may be caused by a number of organisms, including *Streptococcus* species, pneumococci, *Staphylococcus aureus*, *Haemophilus influenzae*, *Moraxella* species, *Neisseria* species, *Pseudomonas* species, and Enterobacteriaceae (including *Escherichia coli* and *Klebsiella* species), among others (Fig. 129-27 and Boxes 129-3 through 129-8).<sup>177-179</sup> Keratitis of bacterial origin is a leading cause of visual loss in the developing world.<sup>180,181</sup> Such conditions as trauma, introduction

**FIGURE 129-27** Suppurative keratitis with a large hypopyon and corneal ulceration. (From Sanford-Smith J: *Eye Diseases in Hot Climates*, 2nd ed. Oxford, Wright Publishers, Butterworth Heinemann, 1990, plate 8.)

of foreign bodies, epithelial defects from xerophthalmia/measles, herpetic keratitis, exposure keratitis, and entropion with trichiasis all predispose affected persons to the development of suppurative keratitis. Corneal scarring, neovascularization, and corneal ulceration/perforation may result (Figs. 129-27 and 129-28).<sup>177</sup> Diagnosis should include a Gram stain and culture of conjunctival or corneal scrapings.<sup>181</sup>

Treatment of bacterial keratitis needs to be urgent and intense. Topical fluoroquinolones or topical cefazolin and gentamicin or tobramycin are usually employed.<sup>10,182</sup> Careful clinical monitoring is required. If the Gram stain or culture result discloses fungal forms or if the keratitis is progressive despite the use of topical antibacterial agents, a topical antifungal agent (such as amphotericin, miconazole, or natamycin) should be employed.<sup>179,183</sup> A mydriatic/cycloplegic is often employed in persons with suppurative keratitis.<sup>10</sup>

The most common causes of acute bacterial conjunctivitis are *Staphylococcus aureus*, streptococci, and *Haemophilus influenzae*. Bacterial conjunctivitis usually resolves spontaneously over 7 to 10 days. Topical application of an antibiotic speeds resolution.

### Bacterial Endophthalmitis

Exogenous bacterial endophthalmitis may result from introduction of organisms through trauma, surgery, or a perforated corneal ulcer. Endogenous bacterial endophthalmitis is secondary to hematogenous dissemination of a systemic infection (Plate 129-5).<sup>184,185</sup> Therapy of endophthalmitis must include intravitreal installation of antibiotics (usually vancomycin and a third generation cephalosporin or amikacin).<sup>10,186</sup> Vitrectomy is beneficial in severe cases. The role of systemic antibiotics in isolated endophthalmitis without systemic infection is controversial.

### Bacterial Orbital Cellulitis

Bacterial orbital cellulitis results from infection/inflammation that occurs within the bony orbit. Orbital cellulitis may result

from contiguous spread from adjacent sinuses, from direct inoculation/trauma, or rarely from hematogenous dissemination. Involvement can result in extensive orbital edema, chemosis, proptosis, endophthalmitis, cavernous sinus thrombosis, meningitis, and brain abscess formation. Subperiosteal and orbital abscesses may be present. Ocular palsies and ophthalmoplegia may result. Treatment involves systemic antimicrobial agents.<sup>10</sup> Abscesses often require surgical drainage. Concomitant sinusitis needs to be excluded and, if present, treated appropriately.

**FUNGAL INFECTIONS****Fungal Keratitis**

The cornea is the most common site of fungal infection of the eye. Fungal keratitis (keratomycosis) can lead to corneal ulceration, corneal scarring, visual loss, and blindness.<sup>178</sup> In the tropics, 25% to 50% of all cases of suppurative keratitis are fungal in origin.<sup>178,187–189</sup> The most common causes

**FIGURE 129-28** Corneal perforation secondary to ulceration. Note prolapse of the iris. (From Sandford-Smith J: Eye Diseases in Hot Climates, 2nd ed. Oxford, Wright Publishers, Butterworth Heinemann, 1990, plate 4e.)

of fungal keratitis are *Aspergillus* species and *Fusarium* species. Others include *Curvularia* species, *Candida* species, *Penicillium* species, and *Cephalosporium* species, among others (see Box 129-3).<sup>177,179,181,183,190,191</sup> Keratomycosis may occur after minor corneal trauma, especially trauma involving vegetable matter. The fungal corneal infiltrate typically has a feathery border and satellite lesions.<sup>183</sup> Corneal scrapings by an ophthalmologist should be performed in all cases of suppurative keratitis. Gram stain and potassium hydroxide wet-mount preparations are economic and effective means of preliminarily establishing whether keratitis is bacterial or fungal in origin and in directing initial treatment. Suppurative keratitis of either mycotic or bacterial origin is an ophthalmic emergency, and therapy should be instituted immediately (see Fig. 129-27). Definitive therapy may be guided by culture results of corneal scrapings. If a preliminary Gram stain does not disclose fungal forms but the corneal lesion is progressive despite the administration of appropriate topical antibacterial agents, strong consideration should be given to the empirical addition of an antifungal agent. Treatment of keratomycosis should be intense and include hourly eye drops with topical amphotericin B (0.15%) and/or topical natamycin. Therapy of keratitis due to *Candida* species may include topical amphotericin or fluconazole. Topical and oral fluconazole may be used as supplemental therapy in the management of candidal keratitis.<sup>183</sup> For keratitis caused by *Aspergillus* species, topical amphotericin or natamycin may be supplemented with oral itraconazole or voriconazole. Topical natamycin should be used in keratitis caused by such organisms as *Fusarium* species, *Penicillium* species, and *Cephalosporium* species. Topical silver sulfadiazine has also been used in the treatment of keratomycosis, especially that caused by *Fusarium* species.<sup>183</sup> The use of steroids should be avoided. Débridement may improve ocular penetration of drugs. Surgical intervention, including cryotherapy, cauterization, penetrating keratoplasty, or conjunctival flaps may be required.<sup>183</sup>

**Aspergillosis**

Aspergillosis can be caused by a number of *Aspergillus* species. Ocular involvement by *Aspergillus* species may result in conjunctivitis that may involve the canalicular lacrimal duct and can result in tear-flow obstruction.<sup>192</sup> Scleritis with ulceration may occur.<sup>193</sup> Keratitis with extensive corneal ulceration may occur.<sup>183</sup> Endophthalmitis may result from posterior progression of keratitis, from traumatic or surgical inoculation, or from hematogenous dissemination (the latter usually occurring in immunocompromised persons or in intravenous drug abusers).<sup>194</sup> Such involvement may present with loss of vision. Iritis, chorioretinitis, retinal hemorrhages, retinal detachment, vitritis, endophthalmitis, perivasculitis, and optical neuritis may occur.<sup>195</sup> Ocular aspergillosis can rarely present as an isolated anterior chamber expansile mass. *Aspergillus* species can involve sinus structures, and such an infection can extend into the orbit. Acute invasive fungal sinusitis can be caused by *A. fumigatus* (although more commonly by fungi of the order Mucorales), usually in immunocompromised persons. Orbital involvement with proptosis and chemosis can occur. A more chronic form of invasive fungal sinusitis, often due to *A. fumigatus*, may occur

in immunocompetent or immunocompromised persons and is associated with the development of orbital apex syndrome: ptosis, proptosis, ophthalmoplegia, neuralgia of the ophthalmic division of the trigeminal nerve, and visual loss.<sup>196</sup> A more chronic, indolent fungal sinusitis, often caused by *A. flavus* and called granulomatous invasive fungal sinusitis, is most commonly reported in Africa and South Asia.<sup>196,197</sup> Involvement is usually in immunocompetent persons, who often present with unilateral proptosis. Surgical intervention, supplemented by amphotericin B, caspofungin, or voriconazole is required.<sup>196</sup> Diagnosis of ocular involvement by *Aspergillus* species is usually based on microscopic examination of tissue preparations and cultures. Topical (0.15%), intravitreal, and systemic antifungal agents (or combinations) are employed, depending on the location of the *Aspergillus* infection.<sup>193</sup> Penetrating keratoplasty may be required for keratomycosis caused by *Aspergillus*; vitrectomy with installation of intravitreal amphotericin is required for endophthalmitis caused by *Aspergillus*.<sup>193,198</sup> Systemic administration of antifungal agents is usually required.

### Candidiasis

Candidiasis can be caused by a number of *Candida* species, of which the most commonly reported is *C. albicans* (see Chapter 83). Ocular involvement by *Candida* species most commonly manifests as chorioretinitis complicating hematogenous dissemination (usually in an immunocompromised host); other manifestations include choroiditis, chorioretinitis, vitritis, endophthalmitis, uveitis, iridocyclitis, keratitis, and infection of the lacrimal system or eyelids<sup>183</sup> (Figs. 129-29 and 129-30). Involvement of superficial ocular structures usually occurs after epithelial disruption, trauma, or surgical manipulation. Patients who successfully recover from candidal chorioretinitis may be at risk for subsequent choroidal neovascularization. Diagnosis is based on microscopic analysis and fungal culture of scraping or tissue samples. Blood cultures may be positive in persons with candidemia. Candidal keratitis should be treated with topical amphotericin or, if *Candida albicans*,

**FIGURE 129-29** Candidal chorioretinal lesion with vitreal extension and overlying vitreal haze. (From Edwards JE Jr, Foos RY, Montgomerie JZ, et al: Ocular manifestations of *Candida* septicemia: Review of seventy-six cases of hematogenous *Candida* endophthalmitis. *Medicine* [Baltimore] 53:48, 1974.)

**FIGURE 129-30** Chorioretinal candidal lesions of the posterior fundus (arrowheads). The optic disk is edematous. Gross specimen, right eye. (From Edwards JE Jr, Foos RY, Montgomerie JZ, et al: Ocular manifestations of *Candida* septicemia: Review of seventy-six cases of hematogenous *Candida* endophthalmitis. *Medicine* [Baltimore] 53:48, 1974.)

topical fluconazole and oral fluconazole. Candidal chorioretinitis will respond to systemic amphotericin. Candidal endophthalmitis should be treated with vitrectomy and intravitreal amphotericin B (irregardless of *Candida* species) and systemic fluconazole (if *Candida albicans*). Systemic flucytosine may be employed during the initial stage of therapy.

### Cryptococcosis

Cryptococcosis is caused by *Cryptococcus neoformans* (see Chapter 80). Ocular involvement during cryptococcal infection usually occurs in the setting of disseminated cryptococcosis, usually with cryptococcal meningitis. Thirty percent to 40% of persons with cryptococcal meningitis have ocular signs or symptoms. The organism can spread directly along the optic nerve sheath and can result in direct cryptococcal invasion of the optic nerve. Papilledema and visual loss are common (Fig. 129-31). Optic atrophy usually results if the

**FIGURE 129-31** Cryptococcal meningitis-associated papilledema. Note hemorrhagic swelling. (From Garrity JA, Herman DC, Imes R, et al: Optic nerve sheath decompression for visual loss in patients with acquired immunodeficiency syndrome and cryptococcal meningitis with papilledema. *Am J Ophthalmol* 116:47, 1993.)

**FIGURE 129-32** Cryptococcal retinovitreal abscess along the inferotemporal arcade, right eye. (From Hiss PW, Shields JA, Augsberger JJ: Solitary retinovitreal abscess as the initial manifestation of cryptococcosis. *Ophthalmology* 95:162, 1988.)

patient survives an acute infection complicated by cryptococcal papilledema. Involvement of the central nervous system during cryptococcosis may result in cranial nerve dysfunction and extraocular muscle paresis.

Hematogenous spread usually involves the posterior pole of the eye and usually occurs in immunocompromised persons, such as those with AIDS or those on steroid immunosuppression. Immunocompetent persons, however, may also be affected. Involvement may be focal or multifocal and may be bilateral. Isolated ocular involvement can occur and may precede systemic manifestations.<sup>199–201</sup> Posterior involvement includes choroiditis, chorioretinitis, neuroretinitis, and endophthalmitis (Fig. 129-32).<sup>200,201</sup> More rarely, anterior uveitis, iridocyclitis, and an iris mass occur.<sup>202</sup> Direct intraocular inoculation of organisms following trauma or surgery may result in rare cases of keratitis and cryptococcal endophthalmitis.

Diagnosis rests on microscopic and culture analysis of aqueous or vitreal samples. Persons with disseminated cryptococcosis may have positive blood cultures, and cryptococcal antigen assays of blood, cerebrospinal fluid, or urine may be positive.<sup>201</sup> Treatment involves fluconazole and/or intravitreal and systemic amphotericin B. Flucytosine may be added during acute management. Repetitive (daily) lumbar punctures with removal of cerebrospinal fluid to control intracranial hypertension are often required. Surgical intervention may be required. Once the infection is controlled, oral fluconazole may be employed. Recrudescence is common, especially in immunocompromised persons. Maintenance fluconazole may be required.

## Histoplasmosis

### *Histoplasma capsulatum*

Ocular involvement due to *H. capsulatum* can take one of three forms, depending on the immunologic status of the affected person: chorioretinal granuloma formation, disseminated histoplasmosis, and presumed ocular histoplasmosis syndrome (POHS).<sup>203</sup> Involvement of the eye by *H. capsulatum* occurs predominantly during hematogenous dissemination (see Chapter 80). Immunocompetent persons may present

**FIGURE 129-33** Acute *Histoplasma capsulatum* choroidal granuloma. (From McMillan TA, Lashkari K: Ocular histoplasmosis. *Int Ophthalmol Clin* 36:180, 1996.)

with a focal chorioretinal granuloma (Fig. 129-33). Such a lesion can present as a tumor-like intraocular mass or as a diffusely infiltrating granulomatous lesion. Conjunctival granulomata have also been reported.<sup>204</sup> Ocular involvement during widely disseminated histoplasmosis is most common among immunocompromised persons, such as those with AIDS.<sup>205</sup> Choroiditis, chorioretinitis, retinitis, optic neuritis, endophthalmitis, iritis, scleritis, and conjunctivitis can occur. Fungal invasion of the central retinal vein has been reported. Inflammatory responses may be minimal in such severely immunocompromised persons.

POHS is thought to occur in persons with strong immunity to *H. capsulatum*.<sup>203,206</sup> It is thought that a previous, perhaps even asymptomatic, episode of histoplasmosis leads to multiple foci of choroidally deposited *H. capsulatum* organisms. A prompt and potent immune response leads to destruction of the organisms and to resultant disciform scar formation (Fig. 129-34). The presumed ocular histoplasmosis syndrome includes the findings of peripapillary or peripheral chorioretinal scars and disciform macular lesions.<sup>203</sup> There is no evidence of active vitreal or aqueous inflammation. A histoplasmin

**FIGURE 129-34** Presumed ocular histoplasmosis syndrome—associated atrophic chorioretinal scars. (From McMillan TA, Lashkari K: Ocular histoplasmosis. *Int Ophthalmol Clin* 36:181, 1996.)

**FIGURE 129-35** Presumed ocular histoplasmosis syndrome—associated choroidal neovascular membrane, macular. (From McMillan TA, Lashkari K: Ocular histoplasmosis. *Int Ophthalmol Clin* 36:182, 1996.)

skin test result is often positive, although evidence of active histoplasmosis is absent. Patients with POHS are at risk for neovascularization that may be complicated by retinal hemorrhages (Fig. 129-35).<sup>203</sup> Loss of vision may be pronounced.

Diagnosis of granulomatous or disseminated ocular histoplasmosis usually rests on demonstration of the organism. *H. capsulatum* may be cultured from the blood in severely immunocompromised persons. Diagnosis of POHS usually rests on fundusoscopic findings and serologic or skin test evaluations. Treatment of active ocular histoplasmosis includes the use of systemic amphotericin B. Intravitreal therapy may also be employed. Itraconazole has poor intraocular penetration and should be used only after control of the active infection has been achieved. Immunocompromised persons may require maintenance suppressive therapy. In POHS, antifungal therapy is not administered. Laser photocoagulation has been demonstrated to lessen loss of vision secondary to choroidal neovascular membrane formation (when such lesions are nonfoveal).<sup>203,206</sup> Careful ophthalmic monitoring of patients with POHS is required. It is controversial whether steroids are of benefit, but they are sometimes employed in the treatment of foveal POHS lesions.<sup>203,207</sup>

### *H. capsulatum* variety *duboisii*

Infection with *H. capsulatum* var. *duboisii* has been reported from Africa and causes a clinically distinct form of histoplasmosis called African histoplasmosis (see Chapter 80).<sup>208</sup> Involvement is usually of the skin, soft tissue, and bone. Lesions are chronic and may present as nodules or expansile cold abscesses. Involvement may present as an isolated lesion or, more rarely, as a systemic infection. Involvement of bones is common. Ocular involvement has been reported due to orbital spread from the bones of the face (Fig. 129-36).<sup>209</sup> Diagnosis is based on microscopic and culture analysis of tissue specimens or abscess contents.<sup>209</sup> Treatment of ocular *H. capsulatum* var. *duboisii* has involved surgical intervention supplemented by systemic antifungal agents.<sup>209</sup>

### Coccidioidomycosis

Coccidioidomycosis is caused by *Coccidioides immitis* (see Chapter 80). Eye involvement may occur during acute coccidioidomycosis but may remain asymptomatic. Fundusoscopic examination in such persons may disclose healed inactive chorioretinal scars that are similar to, but distinct from, those associated with previous histoplasmosis. Symptomatic involvement usually occurs during disseminated disease or during chronic coccidioidomycosis. Primary pulmonary coccidioidomycosis may be associated with phlyctenular conjunctivitis, scleritis, episcleritis, or keratoconjunctivitis.<sup>210</sup> Such manifestations may well represent hypersensitivity reactions and may occur in the presence of erythema nodosum.<sup>210</sup> Immunocompromised persons with disseminated disease may present with conjunctivitis and preauricular adenopathy. Granulomas of the eyelid may occur in disseminated disease.<sup>210</sup> Intraocular involvement during progressive systemic coccidioidomycosis may include iridocyclitis, iris nodule formation, choroiditis, chorioretinitis, and endophthalmitis (Figs. 129-37 and 129-38).<sup>210</sup> Involvement is often granulomatous.<sup>211</sup> Choroidal involvement may present as whitish yellow, slightly raised nodular lesions (see Fig. 129-38). Such involvement of deeper ocular structures may rarely occur in the absence of apparent systemic coccidioidomycosis.<sup>210,211</sup> Involvement of the central nervous system can result in papilledema and

**FIGURE 129-36** Left orbital extension of *Histoplasma capsulatum* var. *duboisii* from facial and orbital bones. A, Pretreatment, showing periorbital swelling. B, Six months after surgery and amphotericin B treatment. (From Olurin O, Adetokunbo O, Lucas MD, et al: Orbital histoplasmosis due to *Histoplasma duboisii*. *Am J Ophthalmol* 68:15, 1969.)

**FIGURE 129-37** Iris nodules due to *Coccidioides immitis*. (From Rodenbiker HT, Gansley JP: Ocular coccidioidomycosis. *Surv Ophthalmol* 24:275, 1980.)

cranial nerve dysfunction.<sup>210</sup> Involvement of the optic nerve may also result in optic atrophy.<sup>210</sup> Choroidal coccidioidomycosis does not appear to be associated with the development of choroidal neovascularization.<sup>210</sup>

Diagnosis is usually confirmed through clinical recognition with histologic examination and culture of tissue specimens, or both.<sup>211</sup> Skin tests and serologic assays are also available. Ocular involvement usually occurs in disseminated disease, and therapy is usually systemically administered. Intraocular involvement should be treated with systemic antifungal agents, usually amphotericin B.<sup>211</sup> After control of the acute infection, systemic fluconazole or itraconazole may be employed. Surgical intervention may be required. Chronic suppressive therapy may be required in immunocompromised persons, such as those with AIDS.

### Blastomycosis

Blastomycosis is caused by *Blastomyces dermatitidis* (see Chapter 80). Ocular involvement during blastomycosis is rare. Most often, involvement of the eye by *B. dermatitidis* manifests as a blastomycotic skin lesion involving the eyelid. The sclera, conjunctiva, and cornea may be involved. Scarring can lead

to ectropion. Hematogenous dissemination may result in direct ocular deposition of organisms, usually in the choroid. Choroidal granulomas may present as small subretinal masses or as diffuse granulomatous lesions with vitritis. Iritis, iris nodules, choroiditis, endophthalmitis, or panophthalmitis may occur.<sup>212</sup> Orbital involvement has been reported. Ocular involvement usually occurs in patients with disseminated blastomycosis, although rare persons may present with apparently isolated ocular involvement. The incidence of the disease does not appear to be increased among immunocompromised persons with AIDS. Diagnosis is confirmed by histologic examination or culture of tissue samples, often of skin lesions.<sup>212</sup> Due to the systemic nature of the infection, ocular blastomycosis should normally be treated with systemic antifungal agents, usually amphotericin B. Once control of the acute infection is achieved, systemic itraconazole or fluconazole may be employed.

### Paracoccidioidomycosis (South American Blastomycosis)

Paracoccidioidomycosis, also known as South American blastomycosis, is caused by *Paracoccidioides brasiliensis* (see Chapter 81). Ocular involvement by *P. brasiliensis* usually involves contiguous spread of an ulceronodular skin lesion that rarely involves the eyelid. Parinaud's oculoglandular syndrome has been reported. Disease is often systemic, and choroidal granulomatous lesions have been reported.<sup>213</sup> Chorioretinitis may occur. Involvement of the central nervous system can lead to granulomatous meningoencephalitis or mass lesions, with resultant cranial nerve dysfunction and ocular palsies. The optic nerves and chiasm may also be involved.<sup>213</sup> Diagnosis is usually one of clinical recognition, histologic examination, and culture analysis. Serologic assays are available. The incidence of *P. brasiliensis* infection is apparently not increased in immunocompromised persons, including those with AIDS.

### Sporotrichosis

Sporotrichosis is caused by *Sporothrix schenckii* (see Chapter 84). Involvement of the eye usually entails conjunctival, adnexal, or eyelid disease. Orbital infection of deeper ocular structures may occur. Ocular involvement may occur

**FIGURE 129-38** Ocular choroidal coccidioidomycosis. Fundus photograph of right eye. *Left*, Small, round, perimacular lesions and large diffuse lesion inferotemporal to the optic disk. *Right*, Typical scattered, discrete, round choroidal lesions nasal to the optic disk. (From Rainin EA, Little HL: Ocular coccidioidomycosis: A clinicopathologic case report. *Trans Am Acad Ophthalmol Otolaryngol* 76:646, 1972.)

with hematogenous dissemination, after trauma (especially that involving vegetable matter/thorns), or after surgical manipulation.<sup>214</sup> Involvement of sinuses and facial bones can lead to contiguous orbital spread. Scleritis, keratoconjunctivitis, corneal perforation, iridocyclitis, iris nodule formation, necrotizing granulomatous chorioretinitis, granulomatous uveitis, optic neuritis, vitritis, endophthalmitis, and panophthalmitis may occur.<sup>214,215</sup> Regional lymphadenopathy may be present. Parinaud's ulceroglandular syndrome may occur. The necrotizing chorioretinitis may mimic that occurring in toxoplasmosis; however, the degree of overlying vitreal inflammation may be less pronounced in sporotrichosis. Hematogenously disseminated sporotrichosis may present with isolated ocular disease. Diagnosis is usually confirmed by microscopic analysis and culture of superficial lesions, intraocular aspirates, or tissue samples. The organism is difficult to grow in culture. Therapy of cutaneous sporotrichosis with external ocular disease may sometimes be treated with systemic itraconazole, potassium iodide, or amphotericin B. Systemic sporotrichosis with deep ocular disease requires intravitreal and systemic amphotericin B.<sup>214</sup> Surgical débridement, enucleation, or both are often required.<sup>214</sup>

### Mucormycosis

Rhino-orbital-cerebral mucormycosis is a clinical entity that may be caused by a number of *Mucorales* fungi, including *Mucor* species, *Rhizopus* species, and *Absidia* species, among others. The same organisms can also rarely be a cause of isolated post-traumatic keratitis in immunocompetent persons. Rhino-orbital-cerebral mucormycosis is characterized by necrotizing sinusitis, usually in a person with insulin-dependent diabetes or who is immunocompromised. Ocular involvement results from contiguous spread of the necrotizing and rapidly progressing fungal process. Orbital cellulitis is the most frequent ocular presentation. Chemosis, proptosis, ptosis, ophthalmoplegia, uveitis, optic neuritis, hypoesthesia of the forehead (cranial nerve V<sub>1</sub>), central retinal artery inclusion, cavernous sinus thrombosis, and orbital apex syndrome may occur.

Diagnosis is usually one of clinical recognition followed by biopsy of intranasal or orbital tissues. An eschar of the hard palate may be evident. Intranasal examination usually

reveals a black eschar due to necrosis of the mucosa/turbinate. Definitive diagnosis rests on microscopic and cultural analysis of tissue samples or discharge. Treatment is urgent and requires aggressive systemic amphotericin B and surgical intervention.<sup>216</sup> If the eye is involved, exenteration of orbital contents may be required (but may sometimes be avoided).<sup>217</sup> Even in preserved eyes, visual loss is usually pronounced and permanent.

Isolated post-traumatic keratitis due to *Mucorales* species may be treated as mycotic keratitis. Systemic therapy and corneal transplantation may be required.

### Entomophthoramycesis

Entomophthoramycesis can be caused by *Conidiobolus* species or *Basidiobolus* species (see Chapter 84). When entomophthoramycesis involves the face, it is characterized by a slowly progressive subacute infiltrative process that usually involves the nose and perinasal sinus areas (Fig. 129-39).<sup>218,219</sup> The infiltrative process can become periocular and can result in inability to open the eyelids. Diagnosis is usually one of clinical recognition and pathologic/culture analysis of subcutaneous tissue samples. Optimal therapy is not known. Oral ketoconazole, amphotericin B, and trimethoprim-sulfamethoxazole may be employed. Surgical resection of infected tissue is often required.

### Facial Mycotic Infections and Fungal Sinusitis

Rare reports of infiltrative or ulceronodular fungal facial lesions have also been reported with chromoblastomycosis, mycetoma, and lobomycosis (see Chapters 78, 79, and 84). Facial involvement may result in eyelid, conjunctival, or lacrimal canal involvement. Phaeohyphomycosis (see Chapter 79) has rarely been associated with keratitis, corneal ulceration, and endophthalmitis after trauma or epithelial disruption. Fungal sinusitis may be caused by phaeohyphomycosis and *Aspergillus* species, *Scedosporium* species, *Fusarium* species, and *Penicillium* species. Fungal sinusitis may also occur with mucormycosis, blastomycosis, coccidioidomycosis, histoplasmosis, and paracoccidioidomycosis, among others. Fungal sinusitis may lead to orbital involvement, which can lead to proptosis, diplopia,

**FIGURE 129-39** Facial rhinoentomophthoromycosis. Facial involvement can extend to the periorbital area and lead to inability to open the eyelids. (From Singh D, Kochlar RR, Seth HN: Rhinoentomophthoromycosis. *J Laryngol Otolaryngol* 90:872, 1976.)

ptosis, epiphora, or an orbital mass. Diagnosis usually rests on culture analysis of tissue samples. Surgical management supplemented by amphotericin B and azole agents such as voriconazole is often required.

### Rhinosporidiosis

Rhinosporidiosis, caused by *Rhinosporidium seeberi* (see Chapter 84), is usually associated with a polypoid (often pedunculated) lesion of the nasal mucosa. The conjunctival mucosa may also be affected (Plate 129-6). Conjunctival involvement is usually unilateral. Scleral melting may result. Lacrimal glands may be involved. Keratitis has been reported.<sup>220</sup> Diagnosis is usually based on histologic examination of resected polyps. Treatment has involved surgical excision and basal cauterization. Adjunctive topical or systemic amphotericin B or dapsone has also been employed.<sup>220</sup>

## PARASITIC INFECTIONS

### Microsporidial Infections: Microsporidiosis

Microsporidiosis may be caused by *Encephalitozoon* species, *Enterocytozoon* species, *Nosema* species, *Vittaforma* species, and *Pleistophora* species (see Chapter 96). *Nosema* and *Vittaforma* species can result in stromal keratitis and keratoconjunctivitis after trauma and direct inoculation of organisms in immunocompetent persons.<sup>221</sup> Such involvement usually results in a prominent inflammatory response.<sup>222</sup> Ocular involvement during disseminated microsporidiosis can occur in immunocompromised patients, especially those with AIDS, and is usually due to *Encephalitozoon hellem*.<sup>223,224</sup> Ocular involvement in disseminated microsporidiosis usually presents as a superficial keratitis with fine to coarse epithelial opacities, mild conjunctivitis, or both (Fig. 129-40).<sup>222</sup> Endophthalmitis has been reported.<sup>225</sup> Diagnosis rests on microscopic identification of organisms in corneal/conjunctival scrapings. In disseminated microsporidiosis, the organism may also be present in urine, stool, and nasal mucosal tissue samples. Treatment of ocular microsporidiosis secondary to

**FIGURE 129-40** Microsporidial epithelial keratopathy: diffuse illumination of the cornea with granular epithelial involvement. (From Yee RW, Tio FO, Martinez JA, et al: Microsporidial epithelial keratopathy in a patient with AIDS. *Ophthalmology* 98:198, 1991.)

**FIGURE 129-41** A lesion of toxoplasmic chorioretinitis showing a cotton-like patch with hemorrhage. (From Kean BH, Sun TS, Ellsworth DM (eds): *Color Atlas of Ophthalmic Parasitology*. New York, Igaku-Shoin, 1991, p 17.)

*E. hellem* in HIV-infected persons has included fumagillin eye drops and systemic albendazole. Ocular involvement by *Vittaforma cornea* and other microsporidia is less responsive to therapy, and surgical intervention/debridement may be required.

### Protozoal Infections

#### Toxoplasmosis

Toxoplasmosis is caused by *Toxoplasma gondii* (see Chapter 97). Ocular toxoplasmosis usually presents as unilateral and painless posterior uveitis with a white-yellow necrotic retinal lesion with uneven pigmentation (Fig. 129-41). Vitreal inflammation may be pronounced in active disease, and retinal tears, hemorrhages, and detachment may occur.<sup>226,227</sup> Satellite lesions may surround a central larger lesion. Vitritis, panuveitis, scleritis, secondary glaucoma, and optic neuritis have been reported.<sup>228</sup> Once the active inflammation subsides, a hypopigmented “punched out” scar with a surrounding area of retinal hyperpigmentation may be present.

Congenital toxoplasmosis is evident in the minority of infected neonates. Ocular involvement in such infections may be bilateral and severe. Chorioretinitis, vitritis, glaucoma, nystagmus, strabismus, ocular muscle palsies, and microphthalmia may occur.<sup>226,229</sup> Infants with congenital toxoplasmosis that is clinically silent at birth often develop clinically evident reactivation chorioretinitis by their second or third decade of life.<sup>230</sup> Reactivation usually occurs along the borders of old lesions or at previously uninvolved sites.

Chorioretinal involvement may be severe, bilateral, and multifocal in immunocompromised persons.<sup>231</sup> In such persons, toxoplasmosis can cause vitritis, uveitis, scleritis, and optic neuritis; involvement of the central nervous system can produce space-occupying lesions that may result in ocular palsies, nystagmus, and visual field defects.

The diagnosis of ocular toxoplasmosis is usually clinical, based on the appearance of the eye. No treatment is required if isolated ocular disease is quiescent and asymptomatic. There is controversy as to whether to treat all immunocompetent

persons with isolated active ocular disease if lesions are small and peripherally based because disease activity is self-limited.<sup>230</sup> Anti-*T. gondii* therapy and concomitant steroids, however, have been shown to decrease the size of active lesions and to result in smaller retinal scar formation. Affected immunocompromised patients, patients with centrally located lesions, and patients with large retinal lesions, pronounced vitritis, or both should all receive systemic anti-*T. gondii* therapy.<sup>230</sup> Therapy should be continued beyond the resolution of active disease. Therapy may need to be long-term or lifelong in immunocompromised persons. The use of concomitant systemic steroids in ocular toxoplasmosis is controversial. Immunocompetent persons often have extensive inflammation and may benefit from the anti-inflammatory effects of steroids. Necrosis is predominantly organism-mediated in immunocompromised patients and steroid use does not appear to benefit such persons.

## Malaria

Ocular involvement during malaria occurs predominantly during infection with *Plasmodium falciparum* (see Chapter 90). The ability of this parasite to cause erythrocyte sludging, vascular congestion, local cytokine release, and local tissue hypoxemia is thought to account for its ability to affect the eye.<sup>232</sup> Such involvement of retinal vessels can lead to retinal sludging, hemorrhage, edema, and exudates. Involvement may be most prominent in the macular area (Figs. 129-42 and 129-43).<sup>233–237</sup> Involvement of ophthalmic and cerebral vessels can result in intraocular ischemia, infarction, hemorrhages, optic neuritis, papilledema, ocular palsies, and cortical blindness. Papilledema during malaria is associated with a marked increase in mortality.<sup>235</sup> An episode of malaria may be complicated by reactivation of herpes simplex keratitis. Diagnosis usually rests on microscopic identification of the parasite in blood. Treatment is systemic (see Chapter 70). Chronic, inappropriate use of the antimalarial agent chloroquine (which is available “over the counter” in much of the

**FIGURE 129-42** *Plasmodium falciparum* malarial involvement of a retinal capillary (arrowhead). Note almost complete occlusion of the vessel lumen by parasitized erythrocytes. (H&E stain; original magnification  $\times 750$ .) (From Hidayat AA, Nalbanian RM, Sammens DW, et al: The diagnostic histopathologic features of ocular malaria. Ophthalmology 100:1184, 1993.)

**FIGURE 129-43** Four deep retinal hemorrhages (two close to the macula, two below and temporal to the optic disk) in a patient with *Plasmodium falciparum* malaria. world) can produce a characteristic “bull’s-eye” retinal pigmentary maculopathy. Visual acuity is often decreased.<sup>238</sup>

## African Trypanosomiasis (Sleeping Sickness)

African trypanosomiasis is caused by *Trypanosoma brucei gambiense* and *T. b. rhodesiense* (see Chapter 92). Ocular involvement during African trypanosomiasis is secondary to trypanosomal infiltration of ocular tissues and can result in mild eyelid edema, conjunctival injection, interstitial keratitis, and uveitis.<sup>239</sup> Stromal opacification and deep neovascularization may occur. Papilledema, ptosis, ophthalmoplegia, and optic neuritis may complicate neuroencephalitis. Diagnosis rests on identification of trypanosomes in blood, in tissue sections, in aspirated lymph node fluid, or in cerebrospinal fluid. Serologic evaluation may be of benefit, especially in persons infected with *T. b. gambiense*. Treatment is systemic (see Chapter 92).

## American Trypanosomiasis (Chagas’ Disease)

The most common and well-recognized ocular feature of American trypanosomiasis, caused by *Trypanosoma cruzi* (see Chapter 93), is Romaña’s sign: a painless, unilateral, pronounced periorbital edema and conjunctivitis that persists for days (Fig. 129-44). Romaña’s sign results from conjunctival inoculation and penetration of infective trypomastigotes from reduviid bug feces. Lacrimal gland involvement and preauricular and regional lymphadenopathy may occur. Romaña’s sign occurs with acute Chagas’ disease, and its appearance

**FIGURE 129-44** Romaña's sign (painless, nonpitting periorbital edema) secondary to *Trypanosoma cruzi* in acute Chagas' disease. (Courtesy of Dr. Bráulio Luna, Institute de Coração, São Paulo, Brazil.)

necessitates the institution of systemic benznidazole or nifurtimox therapy.

### Leishmaniasis

Leishmaniasis is caused by a number of *Leishmania* species (see Chapter 94). Ocular involvement can occur during visceral, cutaneous, or mucocutaneous leishmaniasis. Ocular involvement during visceral leishmaniasis is rare. Keratitis, iritis, papillitis, chorioretinitis, and retinal hemorrhages have all been reported during visceral leishmaniasis and have been noted to improve after the initiation of antileishmanial therapy; however, direct leishmanial involvement of ocular tissues has not been documented.<sup>240,241</sup> Bilateral anterior uveitis and secondary glaucoma have rarely been reported after completion of antileishmanial therapy.<sup>240</sup> Ocular involvement during cutaneous and mucocutaneous leishmaniasis usually results from direct extension of a leishmanial lesion and usually involves a nodular or ulcerative lesion of the eyelid that can extend into the lacrimal gland or onto the conjunctiva.<sup>242–244</sup> Dacryocystitis may also occur.<sup>245</sup> Total ocular destruction may complicate severe cases of mucocutaneous leishmaniasis. Diagnosis is usually based on clinical recognition and microscopic identification of organisms in tissue scrapings or samples. Treatment varies, depending on the type, location, and severity of leishmanial involvement and may be systemic or topical (see Chapter 94).

### Acanthamoebiasis

Acanthamoebiasis may be caused by a number of *Acanthamoeba* species (see Chapter 95). Ocular involvement is usually one of keratitis that follows trauma or contact lens wear. Acanthamoebic keratitis is characterized by pain out of proportion to eye findings.<sup>246</sup> The keratitis is progressive and

**FIGURE 129-45** *Acanthamoeba* keratitis. Note chemosis, double concentric ring of the corneal infiltrate, and a central corneal epithelial defect. (From Hirst LW, Green WR, Merry W, et al: Management of *Acanthamoeba* keratitis. Ophthalmology 91:1106, 1984.)

is often originally misdiagnosed as being herpetic in origin.<sup>247</sup> The corneal stroma often discloses a ring corneal infiltrate (Fig. 129-45). There may be a sterile inflammatory reaction in the anterior chamber. Diagnosis is made by microscopic analysis and culture of corneal scrapings.<sup>182</sup> Treatment is with topical polyhexamethylene biguanide (Baqucil) or topical propamidine isethionate (Brolene, 0.1%).<sup>247</sup> A dibromopropamide isethionate 0.15% ointment may be applied at night.<sup>182,248</sup> Corneal transplantation is often required, but should be deferred until the keratitis is inactive.<sup>182,247</sup>

### Amebiasis

Documented ocular involvement during amebiasis (see Chapter 86) is rare but usually involves an expansile ulcerative lesion of the face. The most frequent site of ocular involvement is the eyelid, but total ocular destruction can occur. Space-occupying amebic lesions of the central nervous system may result in papilledema, ocular palsies, and visual loss. Invasive amebiasis has been associated with keratitis, small retinal hemorrhages, and pigmentary and cystlike changes in the choroid. Such ocular involvement has been reported to improve after the initiation of specific antiamebic therapy; however, direct involvement of the eye by *E. histolytica* in such cases has not been documented. Diagnosis involves molecular or microscopic identification of organisms in stool, intestinal samples, or aspirates of tissue collections. Treatment is systemic (see Chapter 86). Invasive disease requires metronidazole.

### Giardiasis

Direct parasitic involvement of ocular structures during giardiasis (see Chapter 87) has never been documented. Iridocyclitis, choroiditis, retinal and subretinal hemorrhages, and macular changes have been reported in persons with giardiasis and have been noted to improve or resolve after anti-*Giardia lamblia* therapy is initiated, but causality has never been established. Such involvement may represent immunologically mediated reactions or may be secondary to nutritional deficiencies due to *Giardia*-induced malabsorption.

migrate freely within the cornea, anterior chamber, vitreous, retina, choroid, and optic nerve. Dead or dying microfilariae provoke a prominent inflammatory response either relating to microfilarial antigens themselves or to antigens of the endosymbiont *Wolbachia*. Live microfilariae provoke a limited inflammatory response. Ocular onchocerciasis may be anterior (keratitis and iritis) or posterior (chorioretinitis, papillitis, and optic atrophy). The type of ocular disease may depend in part on parasitic strain and variability. Involvement of the anterior eye can result in punctate keratitis with “fluffy snowflake” corneal opacities that represent local responses to dead or dying microfilariae (Fig. 129-46). Such lesions clear without any residua and occur most commonly in young persons. Punctate keratitis can occur spontaneously or after the initiation of anti-onchocercal therapy. Chronic, recurrent, ongoing inflammation may result in a more serious sclerosing

**FIGURE 129-46** Punctate keratitis secondary to onchocerciasis. (Courtesy of Armed Forces Institute of Pathology, Washington, DC, negative No. 75-1622.)

**FIGURE 129-47** Moderately advanced sclerosing keratitis secondary to onchocerciasis. (Courtesy of Armed Forces Institute of Pathology, Washington, DC, negative No. 75-1624.)

keratitis, which usually affects older persons and can result in total loss of vision. Sclerosing keratitis is characterized by a pannus of inflammatory cells and neovascularization that encroaches from the lower, medial, and temporal borders of the cornea (Figs. 129-47 and 129-48). Residents of the hyperendemic Sudano-Guinean savannah are particularly susceptible to this process. Fifty percent of populations who have sustained heavy onchocercal infections for decades may be rendered blind before death.<sup>249</sup> Anterior inflammation may also include iritis. Secondary glaucoma, cataracts, and synechiae may result. The risk of sclerosis, keratitis, or iritis has been associated with the presence and load of microfilariae in the anterior chamber, cornea, and outer canthus of the eyelid.

The pathophysiology of posterior ocular involvement is less well understood. Chorioretinitis and atrophic changes may occur. Atrophic changes have been associated with filarial load and may be the result of low-level, ongoing host-parasite interactions. Chorioretinitis may be severe, may be unilateral, and may often involve the temporal retina and spare the macula in early disease. Pigmentary hyperplasia and

**FIGURE 129-48** Advanced sclerosing keratitis secondary to onchocerciasis. (Courtesy of Armed Forces Institute of Pathology, Washington, DC, negative No. 75-1626.)

**FIGURE 129-49** Extensive chorioretinal degeneration secondary to onchocerciasis with sparing of the macula and optic atrophy. (Courtesy of Armed Forces Institute of Pathology, Washington, DC, negative No. 75-1632.)

atrophy, fibrosis, and neovascularization may be present (Fig. 129-49). Chorioretinitis has not been associated with filarial load. Optic atrophy may be the result of optic neuritis or secondary glaucoma from iridocyclitis.

Diagnosis often involves clinical recognition, skin snip analysis, or serological assays<sup>250</sup> (see Chapter 100). Surgical nodulectomy and identification of the adult worm may also be employed. Ophthalmic diagnosis rests on slit-lamp and fundoscopic examination. Visualized living microfilariae are curved, motile, and transparent and are visible in the anterior chamber and cornea. Dead microfilariae are straight and opacified. Optimal treatment for onchocerciasis involves ivermectin (see Chapter 100).

### Loiasis

Ocular manifestations of loiasis, caused by *Loa loa* (see Chapter 99), relate to migration of adult worms into and around the eyes. Subconjunctival migration is most common (Fig. 129-50). Conjunctival migration results in a foreign-body sensation and conjunctival injection. The worm moves approximately 1 cm/minute. Periorbital swelling and pruritus may occur. Migration of the worm can result in Calabar swelling of the eyelid (Fig. 129-51). Adult worms may rarely migrate across or through the anterior chamber, vitreous, or retina.

Diagnosis rests on visualization of subconjunctival worms, a history of Calabar swellings, or demonstration of microfilariae in blood (see Chapter 99). Eosinophilia may be striking, especially in persons nonendemic to the area of infection. Surgical removal of the adult worm is not necessary, but if performed, may involve the application of a topical conjunctival anesthetic, such as lidocaine to numb the conjunctiva and slow or halt the movement of the worm. After a single small conjunctival incision is made, the adult worm may then be grasped gently with forceps and a small suture may be

**FIGURE 129-50** Adult worm of *Loa loa* visible under the conjunctiva (arrow). (From Kean BH, Sun TS, Ellsworth DM [eds]: Color Atlas of Ophthalmic Parasitology. New York, Igaku-Shoin, p 127. Courtesy of Armed Forces Institute of Pathology, Washington, DC, negative No. 73-6654.)

passed beneath the worm and carefully tied. The worm may then be removed by dissection. Systemic therapy usually involves diethylcarbamazine (see Chapter 99). It should be recalled that areas endemic for *L. loa* and *O. volvulus* overlap. The possibility of coinfection should be considered.

### Dirofilariasis

Dirofilariasis may be caused by a number of *Dirofilariae* species (see Chapter 101). Ocular involvement is most frequently associated with dirofilarial species associated with subcutaneous migration and nodule formation: *Dirofilaria repens*, *D. ursi*, and *D. tenuis* (previously, *D. conjunctiva*).<sup>251</sup> Ocular dirofilariasis usually involves a migrating worm that most frequently invades the eyelid or subconjunctiva or, more

**FIGURE 129-52** A subconjunctival female worm of *Dirofilaria tenuis* (arrow). (From Kean BH, Sun TS, Ellsworth DM [eds]: Color Atlas of Ophthalmic Parasitology. New York, Igaku-Shoin, 1991, p 133. Courtesy of Armed Forces Institute of Pathology, Washington, DC, negative No. 74-6351-2.)

rarely, intraocular structures (Fig. 129-52). Inflammatory reactions and nodule formation, foreign-body sensation, eyelid swelling, ptosis and pruritus, uveitis, and glaucoma have all been reported. Diagnosis is usually based on pathologic examination of a cystlike or inflammatory ocular lesion. Treatment involves surgical removal of the worm.

### Mansonellaiaiasis

Migrating adult *M. perstans* organisms have been found in subcutaneous tissues and can present with *L. loa*-like Calabar swellings (see Chapter 98). Involvement of ocular structures by immature adult *M. perstans* worms can result in conjunctival nodule formation, eyelid swelling, and proptosis.<sup>252</sup> Retinal masses have been reported.<sup>253</sup> Diagnosis involves pathologic identification of adult or immature worms after surgical resection or morphologic identification of microfilariae in blood. Ocular disease has been surgically treated.<sup>252</sup> *Mansonella ozzardi* infections have been associated with keratitis presumably, from migratory microfilariae.<sup>254</sup>

### Bancroftian and Brugian Filariasis (Lymphatic Filariasis)

Lymphatic filariasis may be caused by *Wuchereria bancrofti*, *Brugia malayi*, or *Brugia timori* (see Chapter 98). Ocular involvement during lymphatic filariasis usually results from aberrant adult worm migration to the conjunctiva, resulting in chemosis, pain, and foreign-body sensation. Adult and maturing worms have also been reported in the lacrimal gland, eyelid, anterior chamber, iris, and subretina. Blocked lymphatic drainage may result in chronic elephantiasis of the eyelids. Microfilariae, although usually confined to blood, have also been isolated from the lacrimal gland, anterior chamber, iris, lens, choroid, and retina. Diagnosis involves identification of microfilariae in blood.

**FIGURE 129-51** *Loa loa*-associated Calabar swelling of periocular structures. (From Sanford-Smith J: Eye Diseases in Hot Climates, 2nd ed. Oxford, Wright Publishers, Butterworth Heinemann, 1990, p 185.)

**FIGURE 129-53** A toxocaral granuloma (center) visible on the eye ground. (From Kean BH, Sun TS, Ellsworth DM [eds]: *Color Atlas of Ophthalmic Parasitology*. New York, Igaku-Shoin, 1991, p 112.)

### Toxocariasis

Toxocariasis is usually caused by the canine ascarid *Toxocara canis* but may also be caused by the feline ascarid *T. cati* (see Chapter 103). Toxocariasis may present as visceral larva migrans or as ocular larva migrans, perhaps depending on the load of infecting organisms. Ocular larva migrans results from infection with only one or a few larvae. It is most common in older children and, more rarely, in adults. Ocular involvement relates to the migration of a wandering larva and the granulomatous-inflammatory host response that it provokes (Figs. 129-53 and 129-54).<sup>255</sup> Peripherally based ocular inflammatory masses may result in visual field defects. Centrally located ocular inflammatory masses can lead to a marked decrease in visual acuity. Retinal inflammation and

**FIGURE 129-54** A sagittal section of an eye showing a large toxocaral granuloma. (H&E stain; original magnification  $\times 25$ .) (From Kean BH, Sun TS, Ellsworth DM [eds]: *Color Atlas of Ophthalmic Parasitology*. New York, Igaku-Shoin, 1991, p 112.)

edema may be severe. Migrating larvae can produce retinal scarring and retinal “track” formation. Retinal traction, retinal hemorrhages, and retinal detachment may occur. Rupture of retinally based inflammatory masses or active migration of larva out of the retina and into the vitreous may result in severe, painless endophthalmitis. Migratory larvae can also result in granulomatous uveitis and secondary glaucoma, keratitis, and optic neuritis. Ocular larva migrans due to toxocariasis often presents as a unilateral, painless, white, retinally based mass in a child and thus must be distinguished from retinoblastoma. The manifestations and approaches to the diagnosis and treatment of ocular larva migrans are more fully considered in Chapter 103.

### Baylisascariasis

Baylisascariasis is caused by the racoon ascarid *Baylisascaris procyonis* (see Chapter 106). Baylisascariasis may present with involvement of the central nervous system with severe neurological sequelae. Isolated ocular involvement may also occur and is one of ocular larval migrans.<sup>256</sup> Larval migration in the eye can cause diffuse unilateral neuroretinitis and multiple choroidal infiltrates, a granulomatous retinal mass, retinal and subretinal track formation, retinal scars, retinal hemorrhages, chorioretinitis, vitritis, and uveitis.<sup>257–259</sup> Diagnosis of ocular disease is one of clinical recognition upon viewing the moving larva. Neurological involvement usually involves serologic evaluation employing *Baylisascaris*-specific antigens.<sup>260</sup> Optimal therapy for *Baylisascaris*-associated ocular larval migrans is not known.<sup>260</sup> Photocoagulation and surgical extraction have been successfully employed.<sup>257</sup>

### Ascariasis

Ascariasis is caused by *Ascaris lumbricoides* (see Chapter 109). Ocular involvement by *A. lumbricoides* is extremely rare, but young adult *A. lumbricoides* worms have been recovered from the nasolacrimal duct, presumably after migration up the esophagus into the nasopharynx.<sup>261,262</sup> Treatment of facial/ocular ascariasis involves mechanical removal of the worm; however, systemic therapy should be employed to treat concomitant intestinal involvement.

### Hookworm

Humans may act as a definite host in hookworm infection caused by *Necator americanus* or *Ancylostoma duodenale* or as a dead-end host for canine hookworms such as *A. braziliense* or *A. caninum* (see Chapter 110). Infectious filariform larvae of the latter species can migrate throughout the host and can result in a syndrome of cutaneous larva migrans (see Chapter 103). Migratory hookworm larvae have been reported to involve ocular structures, including the cornea.<sup>263,264</sup>

### Thelaziasis

Thelaziasis is caused by *Thelazia callipaeda* (the oriental eyeworm) or *T. californiensis* (see Chapter 106). The worms inhabit the conjunctival sac and lacrimal system of various mammals.<sup>265</sup> Humans occasionally become infected.<sup>266,267</sup> Adult worms residing in the conjunctival sac of mammalian

hosts release eggs that are ingested by flies. After maturing in the insect vector, worms are regurgitated during a subsequent ocular secretion meal. Adult worms are approximately 2 cm in length. Ocular involvement in humans results in excessive lacrimation, foreign-body sensation, and local discomfort.<sup>268</sup> Corneal and conjunctival scarification can result.<sup>266</sup> Diagnosis rests on identification of recovered worms. Treatment of the disease in humans involves mechanical removal of the worms.<sup>266</sup>

### Dracunculiasis

Dracunculiasis is caused by *Dracunculus medinensis*, the Guinea worm (see Chapter 102). The older literature reported orbital involvement during dracunculiasis; however, the only confirmed case of *D. medinensis* involving ocular structures entailed the isolation of an adult female worm from the conjunctiva of a patient with extensive lacrimation and conjunctival irritation.<sup>269</sup> Therapy of ocular disease involves mechanical removal of the worm.<sup>269</sup>

### Angiostrongyliasis

Angiostrongyliasis is caused by *Angiostrongylus cantonensis* (*Parastrongylus cantonensis*), the rat lungworm (see Chapter 105). Ocular angiostrongyliasis results from ocular migration of worms in various stages of development.<sup>270</sup> Worms can migrate through the anterior chamber and the vitreous and subretinal space, and then can cause eyelid edema, blepharospasm, inflammation of the anterior chamber, iridocyclitis, retinal detachment, and vitritis (Fig. 129-55). Vitreal migration can lead to vitreal fibrosis and resultant retinal distortion and detachment (Fig. 129-56).<sup>271</sup> Angiostrongyliasis-associated eosinophilic meningoencephalitis may be associated with papilledema (often unilateral) and optic neuritis. Cranial nerve dysfunction can result in ocular palsies and ptosis.<sup>272–274</sup> Orbital involvement may result in extraocular palsies and exophthalmos.<sup>272</sup> Intraocular angiostrongyliasis may occur without associated meningitis.<sup>271,275,276</sup> Diagnosis is usually based on the diagnosis of eosinophilic meningoencephalitis

**FIGURE 129-55** *Angiostrongylus cantonensis* in the vitreous cavity. (From Teekhasaene C, Ritch R, Kanchanarany C: Ocular parasitic infection in Thailand. Rev Infect Dis 8:352, 1986.)

**FIGURE 129-56** *Angiostrongylus cantonensis*: fibrous tract formation from the optic head into the vitreous cavity. (From Teekhasaene C, Ritch R, Kanchanarany C: Ocular parasitic infection in Thailand. Rev Infect Dis 8:352, 1986.)

or pathologic examination of migratory worms. Cerebral angiostrongyliasis is usually self-limited. Steroids, analgesics, and repeated removal of cerebral spinal fluid may relieve symptoms. Ocular angiostrongyliasis has been treated with surgical removal of the worm.<sup>272</sup>

### Gnathostomiasis

Gnathostomiasis in humans is usually caused by *Gnathostoma spinigerum* (see Chapter 106). Ocular gnathostomiasis usually results from direct invasion of the eye or surrounding tissues by a migratory larva (Fig. 129-57). Direct invasion of ocular tissue may result in corneal ulceration, iris perforation, subretinal hole formation, optic neuritis, and retinal artery occlusion. The inflammatory response may be pronounced, and uveitis, vitreal hemorrhage, vitritis, and secondary glaucoma can occur.<sup>277,278</sup> Edema and hemorrhage of the eyelid and orbital inflammation may also be prominent (Fig. 129-58). Fibrous reactions and scarring along worm

**FIGURE 129-57** Intraocular gnathostomiasis. *Gnathostoma spinigerum* worm in the anterior chamber with the head end attached to the cornea. (From Biswas J, Gopal L, Sharma T, et al: Intraocular *Gnathostoma spinigerum*. Clinicopathologic study of two cases with review of literature. Retina 14:440, 1954.)

**FIGURE 129-58** Ocular gnathostomiasis in a patient with marked periorbital edema. (From Kean BH, Sun TS, Ellsworth DM [eds]: *Color Atlas of Ophthalmic Parasitology*. New York, Igaku-Shoin, 1991, p 155.)

tracks can result in vitreal fibrosis. Retinal distortion and detachment may result.<sup>272,279</sup> Worms may invade the central nervous system and may provoke eosinophilic meningoencephalitis. Papilledema and cranial nerve palsies may result.<sup>280</sup> Specific diagnosis may be difficult. Inflammation is usually severe. Serologic assays may cross-react with tests for other helminths.<sup>279</sup> Although optimal therapy is not known, systemic disease has been treated with albendazole, mebendazole, and ivermectin. Ocular disease is usually treated with mechanical removal of the worm. Such a procedure not only treats the ophthalmic disease itself but also prevents subsequent penetration of the worm into brain parenchyma.<sup>272,279</sup> In an attempt to decrease inflammation, corticosteroids may be of benefit when used concurrently with surgical intervention.<sup>279</sup>

### Trichinellosis

Trichinellosis is caused by *Trichinella spiralis* and related species (see Chapter 104). Ocular involvement in trichinellosis usually occurs during the invasive larval stage and usually manifests as bilateral palpebral edema. Invasion of ocular musculature and structures by larvae may result in conjunctival chemosis and hemorrhage, photophobia, retinal hemorrhages, optic neuritis, and optic edema. Pain on eye movement may be prominent. Trichinellosis should be considered in any person presenting with bilateral palpebral edema, myalgias, and eosinophilia. Diagnosis is usually one of clinical recognition, serologic assay, or muscle biopsy.

## Helminthic Infections: Cestodes

### Cysticercosis

Cysticercosis is a disseminated infection caused by the larval stage (metacestode: *Cysticercus cellulosae*) of the pork tapeworm, *Taenia solium* (see Chapter 113). Ocular involvement in cysticercosis relates to the intraocular or periocular

**FIGURE 129-59** Ocular cysticercosis. Three cysticerci, one of them evaginated, are visible in the eye. (From Kean BH, Sun TS, Ellsworth DM [eds]: *Color Atlas of Ophthalmic Parasitology*. New York, Igaku-Shoin, 1991, p 180.)

presence of cysticerci (Fig. 129-59).<sup>281,282</sup> The posterior segment of the eye is most frequently involved symptomatically in ocular cysticercosis. Subretinal cysticerci may be quiescent or may provoke prominent inflammatory responses.<sup>272</sup> Retinal edema, hemorrhage, and detachments may occur. Rupture into the vitreal cavity can occur, as can chorioretinitis, vitritis, and vasculitis. Freely floating cysticerci have been noted in the anterior and posterior chambers, and cysticerci may embed on the ciliary body, iris, or optic nerve. Cysticerci may also develop in the conjunctiva, lacrimal glands, and peri-orbital musculature. Cysticerci within the central nervous system may result in papilledema, cranial nerve dysfunction, and ocular palsies. Diagnosis and treatment of ocular cysticercosis and neurocysticercosis are considered in Chapter 113.

### Sparganosis

Sparganosis is caused by migratory plerocercoid larvae of *Spirometra* species (see Chapter 115). Migratory worms can involve ocular structures. The application of fresh flesh (usually frog or snake flesh) as traditional eye poultices can lead to direct ocular deposition of larvae. Invasion of periocular structures in the anterior chamber may occur; however, ocular worms are usually found in the subconjunctiva. Inflammation may be pronounced and proptosis, lacrimation, periocular edema, pain, and pruritus may be intense (Fig. 129-60). Diagnosis involves pathologic identification of removed worms. Ocular therapy involves surgical removal of the worm. No systemic antiparasitic agent has been shown to be of benefit.

### Echinococcosis

Echinococcosis may be caused by *Echinococcus granulosus* (cystic hydatid disease), *E. multilocularis* (alveolar hydatid disease), or related, less common, species (see Chapter 114). Ocular involvement in cystic hydatid disease usually relates to enlargement of a hydatid cyst in the orbital cavity, usually arising from bony structures (Fig. 129-61). Proptosis, exposure keratitis, corneal ulcerations, extensive lacrimation, conjunctival chemosis and injection, impairment of extraocular mobility,

**FIGURE 129-60** Ocular sparganosis with unilateral periorbital edema and chemosis. (From Zhong HL, Shao L, Lian DR: Ocular sparganosis-caused blindness. *Chin Med J [Engl]* 96:74, 1983.)

optic atrophy, and orbital bone erosion may result.<sup>283</sup> Replacement of the vitreous by intraocular cysts has also been reported. Hydatid disease of the central nervous system can result in papilledema.<sup>283</sup> Intraocular disease due to invasive alveolar hydatid disease has also been reported. Diagnosis involves clinical recognition, imaging studies, and serologic assays.<sup>284</sup> Systemic therapy is considered in Chapter 114. Ocular cystic and alveolar hydatid disease should be treated surgically.

### Coenuriasis

Coenuriasis is caused by the cystic larval stage of dog *Taenia* species tapeworms (see Chapter 115). *Taenia multiceps* and *T. serialis* appear to have a tropism for ocular structures and for the central nervous system. Ocular involvement is usually one of a space-occupying cystic lesion. Ocular cysts may occur in the eyelids, conjunctiva, and extraocular muscles. Intraocular cysts may be located subretinally or intravitreally. Proptosis, exposure keratitis, and corneal ulceration may occur. Older and ruptured cysts can provoke a prominent inflammatory response. Panophthalmitis and blindness may result. Diagnosis involves clinical recognition, imaging studies, and histologic examination. Ocular disease is treated with surgery.<sup>285</sup>

## Helminthic Infections: Trematodes

### Schistosomiasis

Schistosomiasis is caused by various *Schistosoma* species (see Chapter 116). During acute schistosomiasis (Katayama fever), eyelid edema may be present. Direct ocular involvement in later disease can be due to egg deposition from portosystemic shunting, passive egg transfer via the vesico-vertebral-central nervous system venous plexus, or by an aberrantly migrating worm pair. Ocular eggs elicit a granulomatous response that may be pronounced. Most confirmed cases of ocular involvement in schistosomiasis have involved conjunctival or lacrimal gland egg-related granuloma formation.<sup>286,287</sup> Choroidal egg-related granulomatous lesions have been reported, and involvement of the optic nerve can lead to optic atrophy.<sup>288–290</sup> Ocular involvement is most frequently reported with *S. haematobium* infection. Aberrantly migrating worms have been found in the superior ophthalmic vein and in the anterior chamber.<sup>291</sup> Diagnosis and treatment of schistosomiasis are considered in Chapter 116. Ocular involvement should be treated systemically.

### Paragonimiasis

Paragonimiasis can be caused by a number of *Paragonimus* species (see Chapter 117). Ocular involvement usually involves aberrantly migrating worms. Mechanical damage can be extensive. Ocular pain due to an actively migrating worm is usually severe and recurrent, but the pain often spontaneously resolves within an hour of onset.<sup>292</sup> Worms can migrate through the eyelid, anterior chamber, and orbit. Retinal hemorrhages and subluxation of the lens can occur. Prominent inflammatory responses can result in hypopyon, uveitis, and secondary glaucoma. Cerebral involvement can

**FIGURE 129-61** Orbital hydatid (*Echinococcus granulosus*) disease with proptosis and conjunctival hyperemia. (From Chana HS, Klauss V, Shah A: Orbital hydatid disease in Kenya. *Am J Trop Med Hyg* 35:992, 1986.)

result in cranial nerve palsies and papilledema.<sup>293</sup> Diagnosis and treatment is considered in Chapter 117. Ocular disease should be surgically treated.

## Ectoparasites

### Pentastomiasis

Pentastomal infection in humans (“tongue worm”) can be caused by *Lingulata serrata* (see Chapter 118). Ocular involvement in pentastomiasis involves migratory nymphs that have been recovered from the anterior chamber. Iritis and secondary glaucoma have been reported.<sup>294</sup> Diagnosis involves histologic examination of recovered specimens. Therapy for ocular disease involves surgical removal of the pentastomid.

### Myiasis

Ocular involvement by the larvae of flies is called ophthalmomyiasis (see Chapter 118). Ocular involvement in humans has been reported with a number of fly species, including *Oestrus ovis* (“sheep bot fly”), *Gasterophilidae* (“horse bot fly” or “horse warble fly”), *Wohlfahrtia magnifica* (“sheep maggot fly”), *Chrysomya bezziana* (“screw worm fly”), *Cordylobia anthropophaga* (“tumbu fly”), and *Dermatobia hominis*, among others.<sup>295,296</sup> Ocular disease occurs from deposition of eggs by flies or by secondary vectors, such as mosquitoes. Larvae emerge and penetrate the periocular and ocular tissues. Ocular involvement of the orbit, eyelid, or conjunctiva is called “ophthalmomyiasis externa.”<sup>297,298</sup> “Ophthalmomyiasis interna” implies that larvae have invaded deep ocular structures (Fig. 129-62). Such involvement may be either anterior or posterior.<sup>299</sup> Larval migration can result in conjunctivitis, keratitis, scleritis, iritis, vitritis, subluxation of the lens, uveitis, and vitreal hemorrhage.<sup>295,300</sup> Subretinal involvement may result in retinal detachment and hemorrhages. Retinal scarring and “track” formation may result. Involvement may be bilateral.

Specific diagnosis is confirmed by pathologic examination of recovered larvae or of subsequently matured flies.

**FIGURE 129-62** Internal ophthalmomyiasis. Funduscopy examination showing a segmented fly larva. Note depigmented, subretinal epithelial tracks. (From Currier RW, Johnson WA, Rowley WA, et al: Internal ophthalmomyiasis and treatment by laser photocoagulation: A case report. *Am J Trop Med Hyg* 52:312, 1995.)

Treatment of ophthalmomyiasis externa involves mechanical removal of the larva(e) with careful searching for the presence of additional intranasal or intraocular larvae. Ophthalmomyiasis interna may be treated with laser photocoagulation or with surgery.<sup>295,301–303</sup> Topical and systemic steroids may be used to minimize local inflammatory reactions.<sup>302,303</sup>

## BLINDNESS AND NONINFECTIOUS TROPICAL OCULAR PATHOLOGY

The World Health Organization estimates that approximately 40 million persons are currently blind worldwide and that over 100 million persons have markedly decreased vision and are at substantial risk of becoming blind. Leading causes of blindness worldwide include cataract formation, trachoma, glaucoma, onchocerciasis, xerophthalmia, diabetic retinopathy, and age-related macular degeneration.<sup>180</sup> Trauma is a leading cause of unilateral blindness worldwide. Blindness due to thermal or chemical burns to the eye may be accidental or intentional. The application of traditional eye medicines and poultices in much of the developing world often exacerbates initial ocular pathology. End-stage ocular damage may result in formation of a markedly shrunken, useless eye (phthisis bulbi; Fig. 129-63). End-stage ocular damage may also result in a marked anterior bulging of the cornea due to a severely weakened cornea and sclera (staphyloma; see Fig. 129-17).

Sunlight can cause a number of ophthalmologic conditions. Intensive prolonged ultraviolet exposure may be associated with cortical cataract formation. Exposure to ultraviolet sunlight is linked to the development of climatic droplet keratopathy, a degenerative condition in which corneal opacifications form in the superficial corneal stroma. This condition may also be associated with extensive puffiness of the eyelids. Formation of a pterygium (a “fleshy wing” of conjunctival/subconjunctival tissue that encroaches on the cornea laterally and medially) may be related to ultraviolet irradiation. Intense, acute exposure to ultraviolet light may also lead to corneal/conjunctival epithelium damage that can present as photophobia, lacrimation, and ocular pain. Direct observation of the sun or exposure to excessive reflective glare can also result in macular damage that may be permanent.

A number of other conditions that may occur in the tropics may also result in ocular manifestations. Deficiency of

**FIGURE 129-63** Phthisis bulbi. Note shrunken, scarred, blind, end-stage eye. Damage is irreversible. (From Sanford-Smith J: *Eye Diseases in Hot Climates*, 2nd ed. Oxford, Wright Publishers, Butterworth Heinemann, 1990.)

vitamin A may result in xerophthalmia. Deficiency of vitamin B complex may result in optic neuropathy. Snake venom from spitting cobras may result in conjunctivitis, keratitis, or both that may be blinding. Argemone–poppy oil intoxication may result in glaucoma and optic nerve atrophy in India and Bangladesh. Local reactions to secretions of blister beetles, millipedes, and centipedes may result in painful conjunctivitis. Improperly prepared cassava can cause cyanide-related peripheral neuritis and optic neuropathy. The vasculopathy of sickle cell disease may result in ocular vascular changes, hemorrhages, scarring, and neovascularization. Reaction to an unknown allergen may result in vernal keratoconjunctivitis, a disorder that is most common in children and results in papillary conjunctivitis involving the tarsal conjunctiva and limbal region.<sup>304,305</sup>

# Neurologic Disease

TOM SOLOMON  
MUSTAPHA DANESI  
FRANK J. BIA  
THOMAS P. BLECK

## INTRODUCTION

Neurologic presentations are more common in the tropics than in other regions and offer particular diagnostic and management challenges. A variety of factors contribute to this increased incidence, including a climate that favors transmission of insect-borne pathogens (e.g., malaria, arthropod-borne viruses, trypanosomiasis); the increased incidence of vaccine-preventable diseases (e.g., tetanus, diphtheria, polio); the impact of human immunodeficiency virus (HIV) on central nervous system (CNS) infections, particularly tuberculous meningitis; and the poverty, overcrowding, and poor sanitation that are risk factors for so many tropical diseases (e.g., cysticercosis, typhoid). Although this chapter focuses on infectious neurologic diseases, noncommunicable neurologic diseases are also more common in the tropics (e.g., motor vehicle collisions and other forms of trauma). The patterns of cerebrovascular disease in many parts of the tropics are catching up with those in the developed world.

## DIAGNOSTIC APPROACHES

Taking a careful history and performing a detailed neurologic and general medical examination are even more important in the tropics than elsewhere because in many tropical settings the availability of diagnostic tools—particularly imaging—is limited. This section concentrates on the approach to the comatose patient, which is often the greatest challenge.

### History

Compared with seeing a patient in more developed nations, getting a history from a patient with a neurologic problem in the tropics can be especially difficult. The patient may have traveled a great distance over many days to arrive at the health facility, and the person accompanying the patient may not know the original history. In addition, it may not be clear what drugs were administered along the way; for example, anti-convulsants given at a clinic on the way to hospital. Obtaining an accurate history about possible seizures is particularly difficult because of the range of terms used in different settings and the ways in which abnormal movements are interpreted. Remember that in many settings seizures may be regarded as

a sign of mental illness or even of possession by evil spirits.<sup>1</sup> Communication problems are often further compounded by language and translation difficulties. It is worth making a special effort to inquire about possible remedies given by a traditional healer. In many parts of the world, the traditional healer is the first port of call, and referral to conventional health-care systems is very much a last resort.

## Examination

It is common to be faced with a comatose patient for whom little reliable history is available. There may be important clues to the cause on examination: check the pockets for any drugs or other information about past medical history; examine the skin for rash, bites (e.g., snakebite), marks of intravenous drug abuse, a healed dog bite (rabies), chancre (for trypanosomiasis); examine the ears and nose carefully for blood or cerebrospinal fluid (CSF) leak consistent with head trauma; feel for lymphadenopathy, particularly in the posterior cervical triangle (Winterbottom's sign in African trypanosomiasis); and smell the breath for alcohol or ketones.

In the neurologic examination, determine the level of consciousness, check for neck stiffness and other signs of meningism (including Kernig's sign—with the patient supine, and the hip and knee flexed, extension of the knee causes pain and neck flexion), and Brudzinski's sign (with the patient supine, flexion of the neck causes spontaneous flexion of the hip and knee); focus on whether there is hemiparesis, brainstem abnormalities (particularly of the pupils, eye movements (spontaneous or elicited), the breathing pattern, or other focal signs.

It should be possible to classify comatose patients into one of four groups (which may overlap):

1. Diffuse encephalopathy (i.e., a reduction in consciousness) with no focal neurologic signs. If the patient is febrile or has a history of fever, think of CNS infection (e.g., cerebral malaria) or a metabolic cause of coma (e.g., diabetic coma, drugs, toxins) with secondary infection such as aspiration pneumonia
2. Encephalopathy with meningism (neck stiffness, or positive Kernig's sign). If the patient is febrile, a CNS infection (especially bacterial meningitis) is likely, but subarachnoid hemorrhages or posterior fossa vascular disorders should also be considered, especially if the onset was sudden
3. Encephalopathy with lateralizing neurologic signs (e.g., hemiparesis). This often indicates supratentorial focal damage; think of abscess, tuberculoma, meningitis with a subdural collection, stroke, or if the history is more insidious, tumor
4. Encephalopathy with brainstem signs. This may indicate pathology within the brainstem itself (caused, for example, by a local infection) or herniation of the brainstem secondary to raised intracranial pressure due to any of the preceding causes.

## Laboratory Investigations

Examination of the cerebrospinal fluid is the single most important investigation for diagnosis of a CNS infection. In industrialized nations, if a patient has deep coma or focal neurologic signs, a computed tomographic (CT) scan is usually

performed before a lumbar puncture to ensure there is no intracranial abscess or other significant type of raised intracranial pressure, since if there is incipient herniation of the brain stem, a lumbar puncture can worsen this situation. However, if CT scanning is not readily available, particularly in patients with deep coma or focal neurologic signs, the benefits of a lumbar puncture in terms of obtaining an accurate diagnosis are often felt to outweigh the risks.<sup>2</sup>

A definitive diagnosis may require radiographic confirmation of a neurologic lesion with skull or sinus films, CT scans, magnetic resonance imaging (MRI) or angiographic studies, myelography, electroencephalography (EEG), electromyography (EMG), nerve conduction studies, or histologic study of muscle biopsy specimens. Infections such as bacterial meningitis can be confirmed by Gram's stain and culture of the infecting organisms obtained from CSF, though pretreatment with antibiotics before patients come to hospital is common. In suspected bacterial meningitis, treatment should not be delayed because a lumbar puncture cannot be performed quickly. Blood cultures should be obtained regardless of whether a lumbar puncture is performed, since they may reveal the cause of the meningitis. Parasitic infection may be confirmed by examination of blood films, sputum, stool, or in some cases, CSF obtained for the identification of adult parasites, larvae, or ova. Serologic studies of peripheral blood or CSF can be useful in confirming certain bacterial or viral infections. Simple rapid diagnostic kits are becoming available for a variety of infections. Many viral CNS infections are now diagnosed by using the polymerase chain reaction, particularly encephalitis caused by herpes simplex virus.

## SYNDROME-BASED DIAGNOSIS

Syndrome-based differential diagnosis is a convenient way to organize the large number of neurologic infections encountered in tropical medicine. Box 130-1 and Table 130-1 present detailed information on the diagnosis of parasitic infections of the CNS.<sup>3-6</sup>

### Meningitides

The various forms of meningitis usually present with fever, headache, photophobia, mental confusion, or seizures. Physical examination shows a febrile patient with neck stiffness on flexion and other indications of meningeal irritation. Signs of raised intracranial pressure, such as papilledema, may be found in some. For infants and very young children, signs of meningeal irritation may not be obvious, and it may present with either seizures in the setting of fever, mildly impaired consciousness or drowsiness, and occasionally a bulging anterior fontanel. Acute bacterial meningitis generally has a rapid onset and progression. In the tropics, meningococcal meningitis usually occurs in epidemics, affecting mainly children and young adults living within arid geographic regions such as sub-Saharan Africa.<sup>7</sup>

Pneumococcal meningitis can present with markedly raised intracranial pressure and coma. It usually occurs in adults and is particularly common in patients with sickle cell hemoglobinopathy, HIV infection, and functional or anatomic asplenia. *Haemophilus influenzae* meningitis occurs

in unvaccinated children or older adults and is associated commonly with seizures linked with fever in children. Complications of bacterial meningitis include cranial nerve palsies, deafness, and subdural effusion in children. The presentations of viral meningitis are typically less fulminant or severe; the infection is commonly due to enteroviruses, such as poliovirus or echovirus. In recent years, there have been large outbreaks of human enterovirus 71 causing aseptic meningitis, and other CNS complications, in the Asia Pacific area.<sup>8</sup>

Subacute and chronic meningitis due to CNS tuberculosis, fungi, or late chronic neurosyphilis have a less fulminant onset and a slow disease progression.<sup>9</sup> However, aseptic meningitis in secondary syphilis mimics acute viral disease and additionally may cause cranial nerve palsies, particularly in HIV-infected patients. In the early phase of tuberculous meningitis, symptoms may be vague with complaints of headache, insomnia, and body pains. Unless there is a high level of suspicion, the diagnosis could be missed at an early stage of the disease, particularly in adults. Later stages are associated with cranial nerve palsies due to basilar meningitis, though presentations with dementia are not unknown. Characteristically, chronic inflammation occurring at the base of the brain also entraps cerebral blood vessels and may lead to vascular compromise and stroke. Hemiplegia is a potential outcome. Focal tuberculous infections (tuberculomas) present as mass lesions and may be mistaken for brain tumors.<sup>10</sup>

Parasitic disease such as acute amebic meningoencephalitis usually presents with features similar to acute bacterial meningitis but with an associated characteristic olfactory involvement based on presumed entry of the organism through the cribriform plate.<sup>11</sup> Seizures and coma rapidly progress in this disease, even in previously healthy persons. *Naegleria fowleri*, the causative organism, is found in warm, freshwater streams and pools, and obtaining a history of such exposure is highly relevant. Motile flagellated amebic trophozoites may be identified during microscopic examination of a wet CSF preparation. *Acanthamoeba* species are more commonly identified as causative organisms in debilitated, immunosuppressed persons, usually producing a subacute or chronic encephalitis. Angiostrongyliasis and gnathostomiasis may cause eosinophilic meningitis, as well as multiple brain abscesses with focal neurologic signs. Strongyloidiasis occurs in specific populations of immunosuppressed persons such as patients given corticosteroids, transplant recipients, or those infected with human T-cell lymphotropic virus type I (HTLV-I). Paragonimiasis may involve the CNS in young children with severe consequences of chronic meningoencephalitis. Trichinosis occasionally involves the CNS, causing seizures, meningoencephalitis, or hemorrhagic infarction from larval invasion of the microvasculature. Cerebral edema and death from brainstem herniation may occur.<sup>3</sup>

### Encephalopathies

Encephalopathy means a reduction in consciousness level, and when this is due to inflammation of the brain substance, the term encephalitis is used. The signs and symptoms of encephalitis include headache, lethargy, stupor, delirium, seizures, hyperreflexia, and spasticity with a positive Babinski sign. Coma and

  - Cytomegalovirus
  - Epstein-Barr virus
  - Enteroviruses
  - Mumps virus
  - Herpes simplex and varicella-zoster viruses
  - Human immunodeficiency virus
  - Arboviruses (e.g., Japanese B encephalitis virus)
  - Rabies
  - Rubeola

**Postviral and Postimmunization Meningoencephalitides**

- Measles, rubella, varicella-zoster
- Measles vaccine, rabies vaccine, yellow fever vaccine

**Parasitic Meningitides and Meningoencephalitides**

- Amebic meningoencephalitis (*Naegleria* and *Acanthamoeba* spp.)
- Strongyloidiasis
- Paragonimiasis
- *Angiostrongylus cantonensis*
- *Gnathostoma spinigerum*
- Trichinosis
- *Toxocara canis* (visceral and ocular larva migrans)
- Trypanosomiasis
  - Trypanosoma gambiense*
  - Trypanosoma rhodesiense*
- *Loa loa* (filarial)

**Brain Abscesses**

- Bacterial (also causing subdural empyema and epidural abscess)
  - Anaerobic bacteria (e.g., mouth flora)
  - Gram-negative enteric and nosocomial organisms
  - Streptococcus intermedius*
  - Staphylococci
- Fungal
  - Immunologically normal host
  - Coccidioidomycosis

## Immunologically impaired host

- Aspergillosis
- Candidiasis
- Zygomycosis (e.g., mucormycosis in diabetic ketoacidosis)
- Parasitic mass lesion of the central nervous system (CNS)
  - Cysticercosis
  - Echinococcus (hydatid cysts)
  - Schistosomiasis (*Schistosoma japonicum*)
  - Amebiasis (*Entamoeba histolytica*)
  - Toxoplasmosis

**Infections with Minimal CNS Inflammation**

- Borreliosis
- Brucellosis
- Ehrlichiosis
- Leptospirosis
- Malaria
- Rickettsial infections

**Infections Producing Brain Stem and Spinal Cord Syndromes**

- Bacterial
  - Spinal epidural abscess
- Viral
  - Human T-cell lymphotropic virus type I-associated tropical spastic paraplegia
  - Poliomyelitis
  - Rabies
- Parasitic
  - Diphyllobothrium latum* (megaloblastic anemia, vitamin B<sub>12</sub> deficiency)
  - Dracunculus medinensis*
  - Schistosomiasis (*Schistosoma mansoni* and *Schistosoma haematobium*)
  - Paragonimiasis

**Infections Involving the Peripheral Nerves and Muscles**

- Leprosy
  - Acute inflammatory polyneuropathy
- Viruses (e.g., Epstein-Barr virus, varicella, etc)
- Bacteria (e.g., *Campylobacter*)
- Toxin-mediated
  - Tetanus
  - Botulism
- Muscle infection
  - Trichinosis
  - Tropical pyomyositis
  - Diabetes-associated and human immunodeficiency virus-associated pyomyositis
  - Necrotizing fasciitis

signs of raised intracranial pressure may be present. There may be clinical clues to the particular virus; for example, tremors, rigidity spasms, and other movement disorders suggest involvement of the basal ganglia, which is often seen in encephalitis caused by flaviviruses such as Japanese encephalitis virus and West Nile virus.<sup>12</sup> Alphaviruses such as Eastern equine encephalitis can cause a similar syndrome.

In herpes simplex type 1 encephalitis, a focal neurologic disorder of the temporal lobe is almost always documented on brain imaging, and characteristic periodic complexes are often observed in the EEG. In African trypanosomiasis, somnolence alternating with insomnia is characteristic, and these patients have a course that evolves to manifestations of abnormal movement and gait, total indifference, and eventually stupor.<sup>13</sup>

**Table 130-1** Parasitic Infections of the Central Nervous System

	Distribution	Exposure	Major Manifestations
<b>Protozoan</b>			
<i>Toxoplasma gondii</i>	Worldwide	Rare meat, cat feces	Focal findings, occasionally diffuse encephalopathy, meningoencephalitis in immunocompromised hosts
<i>Plasmodium falciparum</i> malaria	Tropics	Female <i>Anopheles</i> mosquitoes	Coma, obtundation, personality changes, movement disorders, focal findings (cerebrospinal fluid usually unremarkable)
<i>Entamoeba histolytica</i>	Worldwide	Fecal-oral	Brain abscess
PAM and GAE <i>Naegleria fowleri</i>	Worldwide	Freshwater lakes (nasal, via cribriform plate)	Fulminant and rapidly fatal
<i>Acanthamoeba</i> spp.	Worldwide	Brackish warm water (respiratory, eyes, skin)	Chronic granulomatous necrotizing encephalitis in immunocompromised hosts
<i>Balamuthia mandrillaris</i>	Peru, Venezuela, Mexico	?River	Meningoencephalitis
<b>Helminthic</b>			
Neurocysticercosis ( <i>Taenia solium</i> )	Worldwide	Fecal-oral (ova) (pork meat tapeworm only)	Seizures, hydrocephalic meningitis, cord lesions
Echinococcosis (hydatid disease) <i>Echinococcus granulosus</i>	South-central Europe, Middle East, South America, Africa, Australia, New Zealand	Fecal-oral from dogs, foxes, etc.	Fewer, larger cysts
<i>Echinococcus multilocularis</i> <i>Echinococcus vogeli</i>	North America South and Central America		Invasive polycystic disease (extramedullary >brain)
<i>Trichinella spiralis</i>	Worldwide	Rare pork, bear, horse meat	Focal infections, inflammation, infarction, or hemorrhage
<i>Strongyloides stercoralis</i>	Worldwide	Skin, autoinfection	Immunosuppression causes hematogenous spread of larvae causing brain abscesses, microinfarcts, granuloma formation, or meningitis
<i>Schistosoma japonicum</i>	Orient, Southeast Asia	Swimming in freshwater containing infected snails	Encephalitis, seizures, focal findings
<i>Schistosoma haematobium</i> <i>Schistosoma mansoni</i>	Africa, South America Asia, Africa, Latin America		Myelopathy, seizures Rare cord compression, spinal artery occlusion, myelitis
<i>Paragonimus westermani</i>	Asia	Eating raw freshwater crustaceans	“Soap-bubble” central nervous system (CNS) calcifications with cavitary lung lesions, occasional seizures, meningitis, focal findings
<i>Paragonimus mexicanus</i>	Costa Rica	Crustaceans	Focal CNS hemorrhage
Helminthic causes of eosinophilic meningitis: <i>Angiostrongylus cantonensis</i>	Southeast Asia	Freshwater crustaceans (infected from domestic rat)	Usually self-limited meningitis
<i>Gnathostoma spinigerum</i>	Southeast Asia	Freshwater fish, frogs, snakes, and paratenic poultry, ducks	Meningitis with residual neurologic deficits (45%)
<i>Toxocara canis</i> <i>Baylisascaris procyonis</i>	Worldwide Worldwide	Pica, puppy feces Tree bark contaminated by raccoon feces	Rare meningoencephalitis Rare meningoencephalitis

GAE, granulomatous amebic encephalitis; PAM, primary amebic meningoencephalitis.

Cerebral malaria is a complication of severe *Plasmodium falciparum* infection and is particularly common in children and pregnant women living in endemic areas.<sup>14</sup> Cerebral malaria often rapidly progresses to seizures and coma in febrile patients who go undiagnosed.<sup>15</sup> Prevention is of particular importance for nonimmune adult visitors, who are at even greater risk for this

complication of severe malaria. They must receive prophylaxis or presumptive therapy that covers potentially resistant strains of *P. falciparum*. Severe malaria may also cause hypoglycemia and mimic the early symptoms of cerebral malaria. Quinine administration can accentuate this problem by enhancing insulin release from the pancreas and contributing to hypoglycemia.

## Postimmunization and Postinfectious Encephalitides

Postimmunization encephalitis has occurred following immunization against yellow fever or rabies, especially in the past when earlier vaccines were utilized.<sup>16</sup> Newer vaccines produced from cell culture are less likely to cause such complications. Postviral encephalitis is well described following measles vaccination in older children. It is characterized by a reduced level of consciousness and multifocal neurologic signs, including hemiparesis and paraparesis.

## Brain Abscess and Other Intracranial Mass Lesions

Brain abscess presents with features of raised intracranial pressure, seizure disorders, and focal neurologic deficits but not necessarily with fevers. Brain abscesses are often caused by mixed anaerobic bacteria, but gram-negative organisms are commonly isolated after middle ear or sinus infections and trauma. Hematogenous dissemination of bacteria such as *Staphylococcus aureus* to the CNS may also result in staphylococcal brain abscess formation. Subdural empyema may present with headache, fever, altered mental status, seizures, nuchal rigidity, and focal neurologic deficits. Most subdural empyemas occur as a consequence of contiguous spread from sinusitis, otitis media, or mastoiditis. Rupture of a CNS tuberculoma to produce meningitis is particularly common in the tropics, and there may be coexistent reactivation of pulmonary tuberculosis.

Neurocysticercosis may produce cystic parenchymal lesions and also causes chronic inflammation of the subarachnoid space with resultant hydrocephalus. Amebic brain abscess from *Entamoeba histolytica* occurs generally in a setting of disseminated disease with concomitant liver abscess. Paragonimiasis can produce mass lesions, chronic meningitis, cerebral infarction, and hemorrhage. Hydatid cyst disease causes local inflammation as well as mechanical obstruction of CSF flow with resulting hydrocephalus.

It is useful to characterize some of the more common clinical scenarios associated with parasitic infections of the CNS, since these syndromes often generate requests for tropical medicine consultation from other practitioners. It is relatively easy to produce a rather long list of diagnostic possibilities when a patient comes in with what appears to be a possible mass lesion of the CNS, but discerning one entity from another on a clinical basis in order to direct the remainder of the diagnostic workup is a challenging task for any consultant. The following clinical paradigms can be considered in sorting out just such cases when they present for evaluation.

## Neurocysticercosis

Neurocysticercosis often presents with a new seizure disorder.<sup>17</sup> In the developing world, cysticercosis is one of the most common causes of seizures. In the tropics, patients are often children, who suffer concomitant injuries, such as burns, when seizures occur near open fires.

Pork ingestion is not necessary for the development of cysticercosis. Human ingestion of the ova produced by pork tapeworms poses the threat of neurocysticercosis. Most commonly, the disease is acquired by ingestion of ova that contaminate foodstuffs grown in soil. Rarely, the source of these

ova can be the patients themselves, who may have previously acquired pork tapeworm infection by eating undercooked pork containing the larvae of *Taenia solium*. The ova passed in their stools are produced by adult tapeworms and are potentially infectious to both themselves (autoinfection) and others in the immediate household environment. Within communities of the developed world, where food may be prepared by *T. solium*-infected persons who have recently migrated from endemic areas, employers and families are at risk of acquiring this disease.

Larvae-containing cysticerci infecting the CNS do not result in any single disease pattern. The clinical presentation depends on the intensity of infection; the number, size, and localization of cysts; and the intensity of the immunologic responses to their presence. The cysts expand slowly, and larvae within these cysts eventually die. Inflammation follows, sometimes associated with seizures. The lesions ultimately calcify. If an intraventricular cyst suddenly blocks the flow of CSF, causing obstructive hydrocephalus, rapid deterioration or death may occur. Ocular infections (which may occur in about 20% of cases) should be ruled out before the institution of any antiparasitic therapy to prevent further irreparable ocular damage from additional inflammatory responses. If evidence of ocular infection is present, corticosteroids should be administered prior to the antiparasitic agent.

In the diagnostic workup of patients with suspected neurocysticercosis, CT and MRI have enhanced our ability to diagnose these disorders and have delineated different patterns of disease in adults and children. Adults from an endemic area are more likely to have older calcified lesions, which show very little contrast enhancement on CT scanning. These patients generally will *not* have demonstrable *Taenia* ova in their stools. In contrast, children are more likely to have acute lesions with contrast enhancement secondary to host inflammatory responses. These reactions represent immune responses to degeneration of the parasites themselves and account for the acute presentations with seizures. The therapeutic decisions surrounding the use of antiparasitic agents, and the potential use of corticosteroids during treatment of acute lesions, are based on these differences.

## Echinococcosis (Hydatid Disease)

Although echinococcosis is also characterized by cystic lesions of the CNS, which can be difficult to distinguish from those of cysticercosis, the epidemiology of human infections and clinical presentations differ considerably from those of neurocysticercosis. Echinococcal cysts tend to be larger and fewer in number, and unlike cysticercosis, echinococcal cysts are not usually found in cerebral parenchyma. They are more likely to infect and destroy vertebral bone, resulting in spinal cord compression from their continuous expansion. Hydatid disease of the CNS only occurs in 1% to 2% of human echinococcosis cases, and CNS infections are more common in children. Compression of the spinal cord is the most common CNS manifestation of this disease.

When children or adults with CNS echinococcosis also have a history of contact with dogs or sheep in areas endemic for this disease, the diagnosis of hydatid disease should be considered. The sequence of infection first involves one of several species of cestodes of the genus *Echinococcus* infecting

carnivores, such as dogs. Within the canine gastrointestinal tract, the parasites grow into adult tapeworms, and humans become infected by accidental ingestion of ova excreted by the infected dog, as in the case of the most common species of parasite infecting humans, *Echinococcus granulosus*.

CT scanning or MRI is useful for demonstrating typical extramedullary cord compression and vertebral involvement. As serologic diagnosis becomes more sensitive and specific, a positive antibody titer in conjunction with a typical appearance of cysts on CT scanning or MRI, or vertebral radiographs demonstrating osseous lesions and the appearance of moth-eaten vertebrae, with a supportive epidemiologic history, should suggest the diagnosis once spinal cord and vertebral involvement by large cystic lesions is confirmed.

### Cerebral Paragonimiasis

The pulmonary presentation of infections with the lung fluke *Paragonimus westermani* is easily mistaken for tuberculosis. The appearance of multiple cavitary lesions in a young patient with chronic hemoptysis and CNS symptoms mimics the spread of pulmonary tuberculosis to the CNS associated with tuberculous meningitis. This picture can be even more confusing when the disease occurs in a population that has a high incidence of positive tuberculin skin test reactivity.

However, when a patient is from an endemic area for paragonimiasis, such as Southeast Asia, where crustaceans or their juices are commonly eaten raw, there is the potential for the complex life cycle of this parasite to involve the human host. Children are particularly susceptible to ectopic cerebral infections with these migrating flukes, particularly if infected early in life, since most cerebral infections occur before 10 years of age. The most common neurologic symptoms include seizure disorders, headache, and visual disturbances; the majority of patients in various clinical series of cerebral paragonimiasis have abnormal eye findings. They include impaired visual acuity, homonymous hemianopsia, optic atrophy, papilledema, nystagmus, and pupillary abnormalities.

A clue to the presence of cerebral paragonimiasis may often be found in plain skull films obtained on patients who have cerebral infection with the adult lung flukes. As the ectopic adult flukes degenerate, skull films may show punctate or nodular calcifications, or even advanced lesions with a "soap-bubble" appearance. *Paragonimus* ova can be found in sputum, feces, pleural and peritoneal fluid, or biopsy tissue.

Hence, any clinical presentation that suggests chronic cavitary pulmonary tuberculosis in a young patient with apparent CNS infection, and particularly ocular involvement, might lead to further questioning to obtain the appropriate epidemiologic data indicating that the patient had been at risk for paragonimiasis. Radiologic evaluation with skull films or CT scanning, observation of typical ova, and confirmatory serologic testing aid in diagnosis.

Several patterns of parasitic infections of the CNS lead to rapid consideration of other potential parasitic causes of CNS infections. Patients with intestinal *amebiasis* caused by *E. histolytica* generally do *not* develop a brain abscess unless there is a generalized and disseminated amebic infection. It is extremely unusual to have an amebic brain abscess develop without an antecedent liver abscess in patients with amebiasis.

Even in the presence of an amebic liver abscess, the incidence of brain abscess is usually less than 10%.

Prior to the current acquired immunodeficiency syndrome (AIDS) pandemic, abscess formation due to *Toxoplasma gondii* infection was rare. It was most likely to occur as reactivation of a latent *Toxoplasma* infection in a compromised host receiving chemotherapy for a disease such as lymphoma, which compromised cell-mediated immunity. However, with the emergence of AIDS, toxoplasmosis became the most common opportunistic CNS infection early in the epidemic, and it has been documented in at least 25% of patients. Because the organisms are sensitive to folic acid antagonists, which are now the drugs of choice for prophylaxis against *Pneumocystis carinii* pulmonary infections, the incidence of *Toxoplasma* reactivation has diminished considerably. Previously infected but asymptomatic patients not receiving prophylaxis, whose HIV infections are not under intensive therapy and who present with multiple ring-enhancing lesions on CT scanning or MRI, are likely to have reactivated this infection.

Many anticipated that the AIDS pandemic would result in large numbers of patients chronically infected with *Strongyloides stercoralis* succumbing to disseminated infections. Filariform larvae reach the CNS via hematogenous spread and would occlude small vessels, resulting in microinfarcts, abscesses, or bacterial meningitis (from carriage of bacteria within the larvae). In some cases, the larvae traverse the perivascular spaces to cause granuloma formation in the meninges or parenchyma, as they have in immunocompromised patients such as transplant recipients. To date, this has not been a major problem, with only about 20 such instances described. However, clinicians should be aware of the increasing recognition of disseminated *Strongyloides* infections that occur together with HTLV-I infections and their associated lymphomas. The presence of disseminated strongyloidiasis in a patient with HIV infections should lead to a consideration of potential coinfection with HTLV-I.

### Infections Involving the Brainstem and Spinal Cord

These infections cause paraparesis, paraplegia, or tetraparesis and occasionally cranial nerve dysfunction. In acute transverse myelitis associated with viral infections, fever, backache, leg weakness, sensory disturbances, and sphincter dysfunction may occur. During the acute phase of illness, flaccid paralysis, with absent or reduced tendon reflexes, is observed. Spasticity and hyperactive tendon reflexes occur later in the course of the disease. A sensory level is usually identified at the involved level of the cord. Transverse myelitis may be a nonspecific complication following a number of viral infections. However, some viruses specifically attack the anterior horn cells of the spinal cord to confer an acute flaccid paralysis in which there may be few sensory symptoms and signs. Poliovirus is the classic cause of this syndrome, but other enteroviruses (e.g., human enterovirus 71) and flaviviruses (e.g., Japanese encephalitis and West Nile virus) can also cause a polio-like syndrome.<sup>18</sup>

Cord compression from an epidural abscess produces similar symptoms and signs to transverse myelitis, but MRI or myelography demonstrates evidence of the cord compression. Most patients with a spinal epidural abscess present with focal

spinal back pain aching or tenderness at the level of infection, followed by nerve root pain radiating from the spinal level of involvement. Subsequently, paraparesis with bladder involvement may progress to complete paraplegia.

In spinal tuberculosis, granulomatous arachnoiditis may arise at any level and subsequently cause radiculomyelopathy. Patients present with a combination of nerve root and cord compression. Tuberculous granulomatous masses or abscess formation may be confined to the epidural space and produce cord compression. However, involvement of vertebral bodies, that is, tuberculous spondylitis, may lead to vertebral collapse with spinal cord compression. *Schistosoma mansoni* and *Schistosoma haematobium* may also cause true granulomatous inflammation of the spinal cord associated with spastic paraplegia and anesthetic sensory levels.<sup>19</sup>

Tropical spastic paraplegia is common in some parts of the tropics, such as Jamaica or southern Japan, where HTLV-I infections are more common, and can evolve into a chronic inflammatory disease of the spinal cord. This is a slowly progressive paraparesis with both increased tendon reflexes and Babinski signs, sphincter dysfunction, and sensory impairment. Paraparesis has been reported in paralytic (dumb) rabies, varicella-zoster infections, and herpes simplex myelitis.

## Infections Affecting Peripheral Nerves and Muscles

### Acute Paralysis

Acute inflammatory polyneuropathy (Guillain-Barré syndrome) occurs in children and adults following a wide variety of microbial infections; examples include Epstein-Barr virus, other herpesviruses, and bacteria-causing enteritis, such as *Campylobacter jejuni*. Symmetric weakness of the lower limbs progresses rapidly to involve the upper limbs and later the trunk and the intercostal, cervical, and cranial nerves. Weakness progresses to paralysis and absent tendon reflexes. Disturbances of autonomic functions may occur. In botulism, the clostridial toxins interfere with release of acetylcholine at the neuromuscular junction and cause acute paralysis.<sup>20</sup> Botulism frequently, but not always, produces diplopia and failure of pupillary constriction, which are rarely seen in the Guillain-Barré syndrome. Diphtheria presents as an acute flaccid paralysis weeks to months after a patient has recovered from the acute illness.<sup>21</sup> It is more common in those whose acute illness was severe,

with myocarditis, but can occur in patients whose initial illness was so mild they did not seek medical attention; such cases will be diagnosed only by taking a careful history about a preceding sore throat.

## Chronic Neuropathy

Gradually evolving neuropathy in tropical countries is often due to leprosy, a result of direct invasion of nerves by *Mycobacterium leprae*. In tuberculoid leprosy, where few organisms are present in nerves, patches of superficial sensory loss and granulomatous enlargement of subcutaneous nerves, such as the ulnar, median, peroneal, posterior auricular, and facial nerves, occur in association with sensory or motor deficits. In lepromatous leprosy, lack of resistance to intracellular bacterial growth causes widespread mycobacterial invasion of cutaneous sensory nerves and a symmetrical pattern of pain and temperature loss with anesthesia involving most of the cutaneous surfaces. Since small sensory fibers are predominantly involved, tendon reflexes are usually preserved, but anesthesia leads to widespread tissue injuries and trophic changes that result from loss of innervation.

## Myositis and Other Muscle Diseases

In tetanus, persistent spasms of the skeletal muscles occur owing to the effects of tetanus toxin on the normally inhibitory spinal neurons (e.g., Renshaw cells) which usually function to inhibit the activity of motor neurons.<sup>22</sup> Reflex muscle spasm occurs in response to various visual, tactile, or auditory stimuli. Spontaneous muscle spasms occur in severe cases, and death from respiratory arrest or laryngeal spasm may occur. In trichinosis parasitic muscle invasion causes deposition of larvae in muscle with considerable muscle pain, periorbital edema, and eosinophilia. Staphylococci and streptococci can directly invade muscle to cause bacterial myositis, often a disease of patients with diabetes mellitus but which is now being seen more frequently in association with HIV infection.

## THERAPEUTIC APPROACHES

### Initial Approach

The initial approaches to emergent problems are outlined in Table 130-2.

**Table 130-2 Initial Approaches to Emergent Problems in Patients with Neurologic Dysfunction**

Problem	Approach
Suspected bacterial meningitides	Location- and age-specific appropriate empirical antibiotic therapy
Increased intracranial pressure	Mannitol 0.25 g/kg; hyperventilation to PaCO <sub>2</sub> near 30 torr; corticosteroids (e.g., dexamethasone 10 mg)
Shock	Intravenous fluid support (e.g., saline) and vasopressor support (e.g., norepinephrine, phenylephrine, epinephrine)
Seizures or status epilepticus	If acute treatment required, begin with an intravenous benzodiazepine (e.g., lorazepam or clonazepam), followed by intravenous phenytoin 20 mg/kg
Acute paraplegia or quadriplegia	Consider high-dose methylprednisolone 30 mg/kg
Acute respiratory failure	Endotracheal intubation and mechanical ventilation; if elevated ICP is suspected, premedicate with either intravenous lidocaine 1.0 to 1.5 mg/kg or thiopental 3 to 5 mg/kg

ICP, intracranial pressure; PaCO<sub>2</sub>, arterial carbon dioxide tension.

## Specific Conditions

In *meningitis*, appropriate treatment with antibiotics should be started immediately to minimize neurologic complications and should not be delayed to await imaging studies. The choice of empirical antibiotics depends on the age of the patient, the clinical features, the CSF Gram's stain, and current local epidemiologic factors. The most commonly utilized antibiotic agents include penicillins and second- or third-generation cephalosporins. In children, dexamethasone is often given intravenously (0.6 mg/kg/day) to reduce inflammation, though they were shown to have no benefit in one study in Africa.<sup>23</sup> In *tuberculous meningitis*, corticosteroids are used to minimize complications arising from chronic inflammation and arachnoiditis, particularly at the base of the brain, and have recently been shown to reduce the risk of death.<sup>24</sup> In an accessible *brain abscess*, CT- or MRI-guided aspiration and antibiotics are the treatment of choice. Anaerobic coverage is usually indicated, since mixed anaerobic infections are often the cause of such abscesses and may not be recovered from the abscess for technical reasons. Surgical drainage and excision of the abscess cavity may be necessary when aspiration is not feasible or is contraindicated. Long-term therapy with antibiotics is usual and in rare cases may be the only treatment required.

In *cerebral malaria*, intravenous antimalarials, such as quinine or quinidine, are often used, though drugs such as artemether, based on the Chinese herb qinghaosu, are being used increasingly.<sup>25</sup> Concomitant glucose infusions are important in preventing drug-induced hypoglycemia, which could easily be confused with cerebral malaria. In *cerebral neurocysticercosis*, both oral praziquantel and albendazole treatment are effective in reducing the number and size of brain cysts. Adjunctive treatment is largely symptomatic; *epilepsy* is treated with anticonvulsants, *hydrocephalus* by ventricular shunting, and *cerebral edema* with dexamethasone. *Postinfection or postimmunization encephalomyelitis* usually responds incompletely to corticosteroids. *Acute paraplegia* resulting from transverse myelitis due to viral infections or specifically, HTLV-I, may respond to treatment with corticosteroids. *Tuberculous radiculomyelitis* responds to antituberculous chemotherapy, but *psaos abscess* or *vertebral collapse* may also require drainage, laminectomy, and decompression of the spinal cord. *Tetanus* is treated with tetanus immunoglobulin to neutralize the toxin, metronidazole, wound treatment to kill the causative bacteria, and large doses of intravenous benzodiazepines to relax the involved muscles. In severe cases, tracheostomy, neuromuscular junction blockade, and mechanical ventilation may be necessary.

Whatever the cause of CNS infection, in addition to treating the specific condition attention should be paid to the non-specific complications and sequelae. In particular, secondary pneumonias are common in patients with reduced consciousness; bedsores, spasticity, and contractures are problems in patients bed-bound for any length of time. Good nursing care

and physiotherapy can make an enormous difference to the eventual outcome.

# Approach to the Patient in the Tropics with Anemia

GEOFFREY PASVOL  
SAAD H. ABDALLA

## INTRODUCTION

Anemia is a major problem in tropical areas largely because of interactions among three factors peculiar to these geographic regions<sup>1-3</sup>: (1) a high prevalence of infections and infestations capable of causing anemia, especially those caused by malaria, helminths, tuberculosis, and human immunodeficiency virus (HIV); (2) the common presence of dietary deficiencies; and (3) a high frequency of inherited red blood cell (RBC) disorders that result in anemia. Added to these adverse prevailing conditions is the scarcity or absence of resources for the investigation and treatment of anemia, which leads the practicing physician to place more reliance on observational and clinical skills rather than complex laboratory tests. This chapter outlines a rational approach to the diagnosis and management of anemia in these most challenging and diverse settings.

## DEFINITION

Anemia can be defined simply as a hemoglobin (Hb) value below the reference range for age, sex, and ethnic origin. A reference range is normally determined for a given population using specific standardized and rigorous methods of measurement. In the case of tropical countries, reference ranges are difficult to define because of the common occurrence of concomitant disease and inherited RBC disorders. Ideally, a reference range should be established by measuring Hb in healthy volunteers not seeking medical help. The definition of a healthy volunteer is difficult in this setting because the perception of

health is relative and because a definition that excludes asymptomatic subjects who may have a parasite infection or an inherited RBC disorder is difficult, especially under conditions in which these groups constitute a large proportion of the population.

The World Health Organization (WHO) has devised a definition of anemia<sup>1</sup>:

In children

- 6 months to 2 years, and Hb less than 11 g/dL
- 2 to 12 years, and Hb less than 12 g/dL

In adults

- 13 g/dL for males
- 12 g/dL for nonpregnant females
- 11 g/dL for pregnant females

A definition of anemia incorporated with a more practical approach for use in a tropical setting is shown in Table 131-1. In addition, consideration needs to be given as to whether these anemias develop acutely or over a more prolonged period (chronic). Acute anemias may demand more immediate intervention, such as blood transfusion, whereas compensatory mechanisms may render these interventions unnecessary in the chronic anemias.

## PATHOPHYSIOLOGY

Anemia leads to a reduction in oxygen-carrying capacity and to a reduction in work performance of potentially important economic consequence to the individual and to society. Examples of the socioeconomic importance of anemia in the tropics have been well demonstrated using different methodologies in various settings involving, for example, sugar cutters in Guatemala,<sup>4</sup> latex tappers in Indonesia,<sup>5</sup> and tea pickers in Sri Lanka.<sup>6</sup> In all three examples, the reduction in work capacity was reversed by correction of the anemia. When more severe, anemia can lead to morbidity and sometimes death from heart failure.

The interactions between anemia, its treatment, and susceptibility to infection are complex and subject to controversy. A full description cannot be provided here, but three major arguments emerge<sup>2</sup>:

1. Anemia increases the risk of infection. This has been demonstrated in iron-deficient subjects by several epidemiologic and clinical studies. Other studies have also shown an increased incidence of infections (gastrointestinal, respiratory, and malaria) in subjects with megaloblastic anemia, but it can be argued that infected subjects utilize or lose folate more rapidly and the association is that of increased need in these subjects rather than increased susceptibility. Several studies have demonstrated a reduction in cell-mediated immunity in iron and in folate deficiency.<sup>2</sup>

**Table 131-1** Practical Definition of Anemia Severity

Degree	Possible Consequences	Hb Level (g/dL)
Mild anemia	Minimal or no work or exercise intolerance	>10
Moderate anemia	Some impairment but still able to function	7–10
Severe anemia	Marked impairment of function but not at rest	4–7
Life-endangering anemia	Impending cardiac decompensation, dyspnea at rest	<4

- Correction of anemia may have a deleterious effect on infection (i.e., the converse of No. 1). This concept has been put forward as a possible cause of exacerbation of malaria in malnourished patients when refed. This may be due to the resultant reticulocytosis, leading to an increase in the invasion of RBCs by parasites rather than a direct effect of replenishment of serum iron. Other factors may also play a role, such as the higher incidence of malaria and bacterial infections in refugees, which may be due to displacement and exposure to pathogens to which they have no immunity. The subject is complex, but for a review see Abdalla.<sup>7</sup>
- Anemia may act as a nonspecific protective response to infection or perhaps be a by-product of that response. This view has been put forward in particular in the context of the anemia of chronic disease (ACD, anemia of inflammation, and secondary anemia). The inflammatory response to infection is important as a nonspecific protective mechanism but also results in ACD.<sup>3</sup>

In clinical practice, it is important to place the pathophysiology of anemia in perspective and to tailor investigations and treatment to the degree of anemia.

## MECHANISM AND CLASSIFICATION OF ANEMIA

There are several ways that anemias can be classified. The three major etiologic factors in anemia in the tropics are (1) infections or infestations, (2) dietary deficiency, and (3) inherited disorders (Box 131-1). With some agents, pathogenesis may be multifactorial, as in HIV infection, ACD, and malaria. A more practical laboratory-oriented method is to classify anemias as to whether they are hypochromic and microcytic, normocytic, or macrocytic.

## CLINICAL APPROACH

The recognition of severe anemia is often easy on clinical grounds. Iron deficiency and malaria are the two most common causes of anemia in the tropics. However, there are a number of important points in the history and clinical examination that often enable the clinician to further narrow the diagnostic possibilities.

### History

The geographic locality is obviously important with regard to the prevalence of specific infections and infestations. Such information is particularly pertinent to malaria, hookworm infestation, tuberculosis, HIV infection, and other important but less frequently occurring causes of anemia, such as visceral leishmaniasis and trypanosomiasis. The physician also needs to know local dietary practices and information such as

- The hematinic, protein, and vitamin contents of common staple local foods and their seasonal variation and availability
- Local restrictive diets, such as vegetarianism and veganism
- The feeding practices for infants and young children (e.g., the age at weaning and the weaning foods)

The clinician needs to be aware of the local prevalence of Hb and other genetic RBC disorders, particularly the more common variants, such as sickle cell anemia (SCA), thalassemia,

## Box 131-1 Major Causes of Anemia in the Tropics

### Infection/Infestation

#### Bacteria

- Severe acute or chronic bacterial sepsis
- Tuberculosis

#### Viruses

- Human immunodeficiency virus infection
- Parvovirus (in the presence of hemolytic anemia)

#### Protozoa

- Malaria
- Amebiasis
- Leishmaniasis
- Trypanosomiasis

#### Helminths

- Hookworm
- Schistosomiasis
- Trichuriasis

### Dietary Deficiency

- Iron deficiency
- Folate deficiency
- Vitamin B<sub>12</sub> deficiency
- Protein/calorie malnutrition

### Inherited Disorders

#### Hemoglobinopathies

- Hemoglobin variants: Hb S, C, D, E, etc.
- α- and β-thalassemia

#### Red blood cell enzyme deficiency

- Glucose-6-phosphate dehydrogenase deficiency

#### Red blood cell membrane defects (minor decrease in Hb only)

- Elliptocytosis, spherocytosis
- Southeast Asian (band III) ovalocytosis

glucose-6-phosphate dehydrogenase (G6PD) deficiency, and RBC membrane defects (e.g., Southeast Asian ovalocytosis). Knowledge of the local epidemiology of malaria as well as drug-resistance patterns of this parasite is important.

A specific question that needs to be asked is whether the anemia has been present from birth, suggesting an inherited disorder, or is of recent onset. A detailed gastrointestinal history, particularly with regard to diet and abdominal pain, as well as the color and frequency of the stool, is important. A history of high fevers in the previous few weeks may suggest malaria. The anemia of malaria is particularly common in primigravida and in children younger than the age of 5 years. Mild jaundice may be present in hemolytic conditions. It is important to determine whether the jaundice is intermittent and whether precipitating factors are present, as occurs in G6PD-deficient patients given oxidant drugs. A family history of anemia may be relevant. Bone and joint pains suggest sickling disorders. In women of childbearing age, it is particularly important to determine parity and previous menstrual history. HIV infection should be considered in those in relevant risk groups. People with HIV infection are susceptible to anemia, which may be exacerbated by drugs such as antifolates.<sup>8</sup>

### Physical Examination

The clinical examination often yields little apart from pallor of the nail beds, palms, and mucous membranes of the

mouth and conjunctivae. There may be other features that reveal an etiologic diagnosis. The presence of a high-grade fever in children is especially suggestive of malaria. Koilonychia (spoon-shaped nails) may suggest severe iron deficiency anemia, as may less commonly occurring esophageal and pharyngeal webs. Angular or atrophic stomatitis is most frequently seen in vitamin B<sub>12</sub> or folate deficiency, but it is not specific and may occur in a variety of other vitamin deficiencies. Atrophic glossitis with mild jaundice may be observed in megaloblastic anemias. Hemolytic anemias are also associated with mild to moderate degrees of jaundice often exacerbated by infection but may be confused with viral hepatitis. Signs of peripheral neuropathy are suggestive of vitamin B<sub>12</sub> deficiency.

Splenomegaly, especially in the presence of fever, is suggestive of acute malaria or typhoid fever. Varying splenomegaly occurs in a number of other conditions, including visceral leishmaniasis, hyperreactive malarial splenomegaly, hemoglobinopathies, thalassemia, and lymphomas. Associated features of HIV disease, including cachexia, oral candidiasis, generalized lymphadenopathy, and thrombocytopenia, may provide clues to this diagnosis.

The basic laboratory requirements for the diagnosis of anemia in the primary health care setting should include facilities to measure or carry out the following relatively simple tests:

1. Hb estimation using a spectrophotometric method will confirm the presence of anemia, quantitate the degree of severity according to the criteria described previously (see Table 131-1), and facilitate the monitoring of treatment.
2. Blood film examination is one of the most useful, relatively simple tests to carry out in the investigation of anemia, but it requires investment of two types: the acquisition of a microscope of reasonable quality with an adequate light source and a person with sufficient basic training capable of recognizing the more important common changes. Examination of blood smears (including a thick film) remains the gold standard in the diagnosis of malaria, identification of the infecting species, and assessment of the degree of parasitemia. Occasionally, trypanosomes, microfilariae, or spirochetes may be seen on the film. The thin blood film provides a starting point in the diagnostic algorithm because it can be used to divide anemia into a number of useful diagnostic categories:
  - a. *Microcytic hypochromic anemia*: The RBCs are small or there is an increase in the normal area of central pallor in the cells (normal, up to one-third of the cell diameter). Microcytic hypochromic anemia is most commonly seen in iron deficiency (Fig. 131-1), thalassemia (Fig. 131-2), and, occasionally, ACD.
  - b. *Normocytic, normochromic anemia* is often found in ACD, which in a tropical setting is most often due to infection rather than inflammatory or neoplastic conditions. It is also seen in acute blood loss, hypersplenism, certain hemolytic anemias, and anemias due to the underproduction of RBCs (e.g., aplastic anemia and bone marrow infiltration).
  - c. *Macrocytic anemias* may be of two major types. Oval macrocytes and hypersegmented neutrophils (neutrophils with more than five lobes or 5% with five lobes) are suggestive of a megaloblastic anemia,

**FIGURE 131-1** Severe iron deficiency anemia. Peripheral blood film obtained after partial treatment with oral iron. Note the population of normally hemoglobinized red blood cells and another with extreme hypochromia. Note also the single elongated red blood cell sometimes referred to as a “pencil cell.”

such as vitamin B<sub>12</sub> or folate deficiency, whereas round macrocytes without hypersegmented neutrophils occur in the nonmegaloblastic macrocytic anemias seen in alcoholism, liver disease, hypothyroidism, and other disorders (Fig. 131-3).

Considerable additional practical information may be obtained from the blood film, such as the following:

- a. *Polychromasia*: The presence of polychromasia (diffuse bluish discoloration of the RBCs) correlates with the presence of reticulocytes. Polychromasia suggests that the marrow is responding appropriately to anemia in conditions such as hemorrhage, hemolysis, and hematinic replacement. The absence of polychromasia in the face of anemia suggests a dietary deficiency state or marrow suppression as a result of some other cause (e.g., infection or drugs).
- b. *Abnormal RBC shape*: Abnormally shaped RBCs may be found, such as sickle cells in SCA, spherocytes in spherocytosis, or irregularly contracted RBCs suggestive of oxidant damage as in acute hemolysis

**FIGURE 131-2** Thalassemia major. Blood film from an inadequately transfused patient with numerous nucleated red blood cells. There are a small number of poorly hemoglobinized red blood cells and some target cells, but the majority of red blood cells are normal ones from the transfusion.

**FIGURE 131-3** Severe megaloblastic anemia. Peripheral blood film showing poikilocytosis and an oval macrocyte. The single neutrophil has a nucleus with six lobes and is hypersegmented.

following infection or oxidant drug treatment in patients with G6PD deficiency. RBC fragments may be seen in microangiopathic hemolytic anemias (Fig. 131-4). Other abnormal cells include elliptocytes (in hereditary elliptocytosis), pencil cells (in iron deficiency), and teardrop cells (in thalassemias and bone marrow infiltration such as myelofibrosis or bone marrow secondaries).

3. *Microscopic examination of the stool* for cysts and ova of parasites is important to exclude worm infestation, especially hookworm and *Trichuris* spp. infestations.
4. *Tests for fecal occult blood* can be carried out to exclude gastrointestinal hemorrhage as a cause of the anemia.
5. *A therapeutic trial:* Where resources are limited, it may often be cost-effective or necessary to embark on a therapeutic trial in the management of anemia that may help establish an etiologic diagnosis. Such a trial may involve, for example, an antimalarial, iron, or both.

### Further Investigations

In the primary health care setting with limited facilities, undiagnosed or unresponsive cases, or those requiring special

treatment such as blood transfusion, may be referred to a center with access to facilities for further investigation. Investigations may include the following:

1. *Electronic cell count:* An electronic cell counter will provide RBC indices: mean corpuscular volume (MCV), RBC count, mean corpuscular hemoglobin (MCH), mean corpuscular hemoglobin concentration (MCHC), a white blood cell count (with or without a differential), and platelet count. The RBC indices will confirm whether the anemia is microcytic, hypochromic; normocytic or normochromic; or macrocytic.
2. *Examination of the bone marrow:* The bone marrow examination needs to be interpreted by someone who has special training in the field. The information obtained may not always be diagnostic but will assist in defining the cellularity of the marrow and provide a semiquantitative estimate of body iron stores. The marrow will indicate whether erythropoiesis is microcytic, micronormoblastic, megaloblastic, or dysplastic. Marrow infiltrations, for example, by malignancy or infection such as leishmaniasis, can be detected. Marrow examination will also help define the maturation of the myeloid and megakaryocytic series. The bone marrow findings in some of the more common conditions are as follows:

#### a. Microcytic hypochromic anemias

- Iron deficiency demonstrates micronormoblasts with absent iron stores on Perls' staining (an iron-specific reagent) and no hemosiderin granules in erythroblasts (Fig. 131-5).
- In the thalassemias, the erythroblasts show poor hemoglobinization with hemosiderin granules present in erythroblasts, sometimes both large and excessive in number.
- ACD may be hypochromic with an increase in storage iron but an absence of hemosiderin granules in erythroblasts—the so-called iron utilization block.
- Sideroblastic anemias show increased iron stores with characteristic “ring sideroblasts.”

**FIGURE 131-4** Sickle cell anemia. Peripheral blood film showing elongated red blood cells that have pointed ends and no central pallor. Not all cells have the classic curved sickle shape. Note the nucleated red blood cells and the Howell-Jolly body, indicative of hyposplenism.

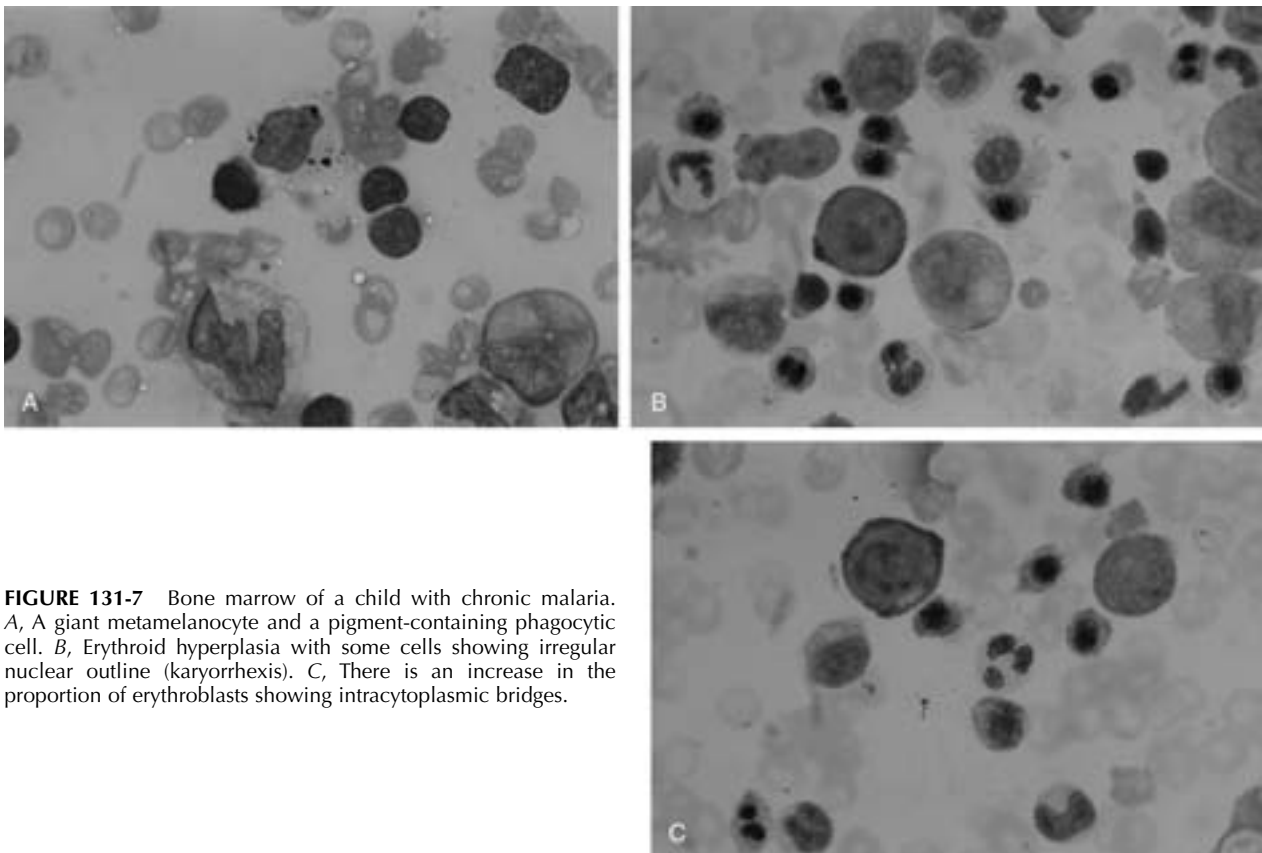

**FIGURE 131-5** Severe iron deficiency anemia. Bone marrow film. Red blood cell precursors show micronormoblastic erythropoiesis. The changes are seen in intermediate and late erythroblasts and consist of cells that are smaller than normal with poor irregular hemoglobinization and, in one case, basophilic stippling.

**FIGURE 131-6** Severe megaloblastic anemia. Bone marrow films showing megaloblastic changes of the erythroid series consisting of erythroblasts that are larger than normal, asynchrony of maturation in which the cytoplasm is more mature than the nucleus, and a rather grainy erythroblast nucleus (A). In addition, there is a giant metamyelocyte that is twice the size of a normal metamyelocyte and has a contorted nucleus (B).

- b. *Macrocytic anemias*: Macrocytic anemias (as judged from the blood film) can be classified on the basis of the bone marrow appearance:
  - Megaloblastic anemia, with megaloblastic changes in the erythroblasts and giant metamyelocytes due to vitamin B<sub>12</sub> or folate deficiency (Fig. 131-6).
  - Normoblastic hemopoiesis, as occurs in liver and thyroid disease and alcoholism.
- c. *Normocytic anemias*: In normocytic anemias, it is important to establish whether the cellularity of the bone marrow is low, normal, or increased with regard to erythroblasts and incidental other cell types:
  - A hypocellular bone marrow is characteristic of aplastic anemia consequent to drugs such as chloramphenicol or following hepatitis B infection.
  - A selective reduction in erythropoiesis but with normal myelopoiesis is found in parvovirus infection and other more rare causes, such as selective RBC aplasia.
  - A normocellular bone marrow is found in a variety of anemias, including ACD.
  - A hypercellular bone marrow is found in hemolytic anemias, leukemias, megaloblastic anemias, and dyserythropoietic anemias, congenital or acquired (Fig. 131-7).

**FIGURE 131-7** Bone marrow of a child with chronic malaria. A, A giant metamelanocyte and a pigment-containing phagocytic cell. B, Erythroid hyperplasia with some cells showing irregular nuclear outline (karyorrhexis). C, There is an increase in the proportion of erythroblasts showing intracytoplasmic bridges.

3. *Investigation of hemoglobinopathies:* Investigation of hemoglobinopathies is important in geographic areas where Hb disorders are common. Tests include the following:
  - a. The sickle solubility test (using sodium metabisulfite) is a simple test based on the insolubility of Hb S in the reagents used. It is advisable to carry out Hb electrophoresis in cases with a positive solubility test to distinguish between patients with sickle cell trait (AS), SCA, or other compound heterozygotes such as S- $\beta$ -thalassemia and SC. The limitation of the sickle solubility test is that it may not detect sickle Hb at low levels (<20%) and is therefore of no use in screening neonates and infants up to 6 months of age when the concentration of HbS is low.
  - b. Hb electrophoresis will confirm the presence of Hb S and other major structural Hb variants, such as Hb C, D, and E, and also distinguish between hetero- and homozygotes. Hb electrophoresis will also detect fetal hemoglobin (Hb F) levels higher than approximately 2%.
  - c. Quantitation of Hb F using an alkali denaturation method is important in the diagnosis of  $\beta$ -thalassemia major and intermedia.
  - d. Quantitation of Hb A2 using a column elution method is important to diagnose  $\beta$ -thalassemia trait because it is higher than 3.5% in carriers. Accurate diagnosis is relevant in areas where genetic counseling is an important strategy in preventing  $\beta$ -thalassemia major.
4. *Serum ferritin or serum iron and transferrin:* A low serum ferritin or a low serum iron with a raised transferrin suggests an iron deficiency anemia, whereas a low serum iron and low transferrin suggest a secondary anemia (e.g., to infections or inflammation).
5. *Vitamin B<sub>12</sub> and RBC folate assays:* Serum vitamin B<sub>12</sub> levels are usually low in megaloblastic anemias due to vitamin B<sub>12</sub> deficiency, but they can be low without anemia in vegans. RBC folate is a more stable measure of storage folate than labile serum folate and shows a moderate to severe reduction in folate deficiency. Care must be taken in interpreting the results because folate can be reduced in vitamin B<sub>12</sub> deficiency.
6. HIV testing is crucial because a positive test will have considerable management implications.

## IMPORTANT ANEMIAS IN THE TROPICS, THEIR DIAGNOSES, AND THEIR MANAGEMENT

### Anemia of Malaria

In areas of high endemicity, severe anemia associated with malaria most commonly occurs in children up to 5 years of age, in whom it can be severe and sometimes fatal.<sup>9,10</sup> Severe anemia most commonly occurs in a younger age group (often <2 years) than in those suffering from cerebral malaria. In contrast, in areas where the occurrence of malaria is epidemic rather than endemic, the age distribution of malarial anemia is less well defined and it may also occur in adult semi-immune people, especially in primigravidas. The importance of anemia

as a cause of death in malaria may well be underestimated because of the difficulty in diagnosis.<sup>11</sup> Attributing malaria as the cause of anemia in a tropical setting is often difficult. Some sources have included a minimal arbitrary Hb and parasitemia (<5g/dL in the presence of parasitemia >10,000/ $\mu$ L) to define severe malarial anemia. However, this definition should be regarded as being for research rather than clinical purposes.

The pathogenesis of the anemia of malaria is both complex and multifactorial but is largely due to hemolysis of infected and uninfected RBCs because the decline in Hb is often far in excess of what can be accounted for by the loss of infected RBCs alone.<sup>12</sup> It is usually normochromic, normocytic.

Two clinical patterns predominate in the development of anemia in malaria: severe acute malaria in which anemia supervenes<sup>13</sup> and anemia that has developed insidiously.<sup>9</sup> In the first, patients suffering a severe acute attack of malaria, and who are seen early after the onset of clinical symptoms, are initially not anemic, nor do they have splenomegaly. However, anemia may develop dramatically during the course of infection, which has been associated with a shortened survival of uninfected RBCs, sometimes well after parasites have disappeared from the blood film.<sup>14</sup> The cause of anemia in malaria in these acute episodes is probably multifactorial and may include inhibition of erythropoietin secretion, which is low and associated with an initial poor reticulocyte response.<sup>15</sup>

The second pattern of malarial anemia in the context of malaria occurs particularly in endemic areas.<sup>9</sup> These patients, usually children, become gradually anemic, often without a clear history of repeated attacks of malaria.<sup>16</sup> The history may be one of intermittent fevers and general symptoms of ill health occurring insidiously over weeks rather than days. Splenomegaly of varying degree may be present and the peripheral blood film may show minimal parasitemia with only the presence of gametocytes and malarial pigment within phagocytic cells as evidence of a past infection. The bone marrow often shows the picture of dyserythropoiesis,<sup>9</sup> with multinuclearity of erythroid precursors, mitotic figures, and intercytoplasmic bridging between dividing cells (see Fig. 131-7). In functional terms, these appearances are associated with ineffective erythropoiesis (i.e., the marrow is active but not producing functional red cells). Unlike the acute situation, erythropoietin levels are increased.<sup>17</sup>

Great difficulty remains in attributing the relative roles of each mechanism that contributes to the development of the anemia of malaria, such as intravascular hemolysis, extravascular clearance of RBCs, and marrow dysfunction. The major mechanisms are those of RBC destruction and decreased RBC production. The former includes loss of infected cells by rupture or phagocytosis, removal of uninfected cells due to antibody sensitization or other physicochemical membrane changes, and increased reticuloendothelial activity, particularly in organs such as the spleen and bone marrow.<sup>9,10</sup> Shortened RBC survival may persist well after parasite clearance<sup>14</sup> and may be related to reduced RBC deformability.<sup>18</sup> Decreased production tends to predominate in acute infections and dyserythropoiesis in more prolonged infections.<sup>19</sup> Successful eradication of the malarial parasite is paramount in the management of this anemia. Malaria on its own does not result in iron or folate deficiency, although there is evidence that children given iron but not folate at the time of an acute attack have higher mean

Hb levels at follow-up.<sup>20</sup> Blood transfusion may occasionally be required in selected severe cases, although most patients have a brisk increase in Hb levels once the malaria has been successfully treated.<sup>21</sup> There is insufficient evidence concerning whether giving blood routinely to children with severe anemia reduces death.<sup>22</sup> A suggested guideline for transfusion in severe malarial anemia, based on Hb level, a safe blood supply, and the presence of severe complications (notably respiratory distress), has been proposed.<sup>23</sup> Insecticide-treated bed nets may have a role to play in the reduction of malaria, especially in infants and young children.<sup>24,25</sup>

### Anemia of Human Immunodeficiency Virus Infection

Anemia is common in patients with HIV infection and present in almost all patients with acquired immunodeficiency syndrome (AIDS), but it is often only mild ( $>10$  g/dL).<sup>8,26</sup> The anemia is often normochromic and normocytic, with low reticulocyte counts and erythropoietin levels but normal or increased iron stores and serum ferritin levels. The cause is multifactorial and complex. The anemia may be even more severe in the presence of mycobacterial infections (*Mycobacterium tuberculosis* and *Mycobacterium avium* complex), fungal infections (e.g., cryptococcal), persistent parvoviral B19 infection, lymphoma, and as a result of many of the drugs used in treatment. Particularly important drugs in the cause of anemia in HIV infection are the antiviral drugs such as zidovudine but also numerous other antiinfective agents, such as dapsone, sulfonamides, primaquine, isoniazid, rifampicin, pyrimethamine, and trimethoprim. Blood loss and microcytosis occur when the gastrointestinal tract is involved with Kaposi's sarcoma, cytomegalovirus, or lymphoma.

### Nutritional Anemias

Nutritional anemias result from the discrepancy between the supply of and the demand for specific nutritional elements. The causes may be dietary or may be due to excessive loss or increased demand for these substances.

#### Iron Deficiency Anemia

Iron deficiency is probably the most common cause of anemia worldwide<sup>27</sup>; the major causes of iron deficiency in the tropics are shown in Box 131-2. This deficiency predominates because of the extremely tight regulation of iron absorption by the intestinal mucosa and because of the generally poor bioavailability of iron from most diets in tropical areas. In addition, local factors may contribute to negative iron balance, such as hookworm, schistosomiasis, and other gut infestations. Iron status and iron deficiency may be evaluated using a number of indicators (see Box 131-2).

The differential diagnosis of a hypochromic anemia may require additional investigations, such as Hb A<sub>2</sub> estimation (to exclude  $\beta$ -thalassemia trait) or Hb F estimation (supportive of a diagnosis of  $\beta$ -thalassemia major or intermedia), or by bone marrow examination (Table 132-2). The true incidence of iron deficiency in the population may be overestimated or underestimated according to the measures used to define iron deficiency.

### Box 131-2 Causes of Iron Deficiency in the Tropics

#### Reduced Intake

Late weaning  
Poor diet

#### Increased Demand

Growth  
Childhood  
Adolescence  
Pregnancy  
Blood loss  
Menstruation  
Gastrointestinal  
Hookworm  
Schistosomiasis  
*Helicobacter pylori* infection  
Trichuriasis  
Other causes found worldwide  
Hiatal hernia  
Peptic ulcer  
Aspirin  
Hemorrhoids  
Malignancy

#### Reduced Absorption

Malabsorption  
Tuberculosis  
Lymphoma  
Giardiasis  
Bacterial overgrowth  
Celiac disease (uncommon)

In general, using a single indicator is often unreliable and extensive studies in different areas of the world are difficult to carry out. Often, a therapeutic trial relying on the knowledge that iron deficiency may be the most common anemia in the population is the only practical management strategy.

#### Folate Deficiency

Folate is found in most foodstuffs, especially in liver, other meats, green vegetables, and some fruits, and it is destroyed by prolonged boiling. Absorption occurs throughout the small intestine.<sup>2</sup> Folate deficiency is therefore rarely due to dietary deficiency and may be due to increased utilization, as occurs in pregnancy, lactation, and malabsorption states. Folate is essential for metabolic functions involved in methyl group transfer and is utilized in nucleic acid synthesis. Deficiency manifests as megaloblastic anemia and also leads to mucosal atrophy.

Serum folate is labile and reflects a transit pool of folate that may be depressed to very low levels within a few weeks on a deficient diet. RBC folate, on the other hand, represents a storage pool formed during erythropoiesis and therefore changes more slowly after deprivation than serum folate. Folate stores usually last 4 or 5 months, after which deficiency occurs. The diagnosis of anemia due to folate deficiency is based on the presence of a macrocytic anemia with oval macrocytes and hypersegmented neutrophils on the blood film and a megaloblastic bone marrow together with a low RBC folate.

**Table 131-2** *Differential Diagnosis of Hypochromic Anemia in the Tropics*

Indices	IDA	ACD	Thalassemia Trait ( $\alpha$ or $\beta$ )
Degree of anemia	Any	Rarely <9 g/dL	Mild
MCV	Reduced (<76 fL or $\mu^3$ )	Normal or reduced	Very reduced
MCH, MCHC	Reduced	Reduced	Reduced
RBC count	Normal or reduced	Normal or reduced	Increased
RDW	Increased	Normal or increased	Normal or increased
Blood film	Microcytic, hypochromic	Microcytic, hypochromic; may be normochromic, normocytic	Microcytic, hypochromic; teardrop cells, basophilic stippling, target cells
Serum iron	Reduced	Normal or reduced	Normal
Serum transferrin	Increased	Reduced	Normal
Iron-binding saturation (%)	Very low	Low	Normal
Serum ferritin	Reduced	Normal or increased	Normal
Bone marrow	Mildly hypocellular	Normocellular or hypocellular	Mildly hypercellular
	Micronormoblastic erythropoiesis	Hypercellular when neutrophil leukocytosis is present	Some dyserythropoiesis
Serum transferrin receptor	Absent marrow iron	Marrow iron present	Present
Response to therapeutic trial of iron replacement	Specific for iron deficiency	Normal	Normal
Other	Good	None except when IDA and ACD coexist	Potential iron overload
		Raised ESR	

ACD, anemia of chronic disease; ESR, erythrocyte sedimentation rate; IDA, iron deficiency anemia; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; RBC, red blood cell; RDW, red blood cell distribution width (index).

Folate deficiency may arise acutely during pregnancy, during acute alcohol intake with a poor diet, and in patients in intensive care in whom severe deficiency may occur with pancytopenia but with normal levels of RBC folate. This picture may also be seen when patients with borderline folate stores are given antifolate drugs, which include sulfonamides and antimalarials such as pyrimethamine and proguanil. Folate deficiency is easily treated with 5 mg/day of folic acid. This pharmacologic dose is easily absorbed and should correct any deficiency. Prophylactic folate should be given to pregnant women and patients with chronic hemolytic anemias such as SCA in which there is increased RBC turnover.

### Vitamin B<sub>12</sub> Deficiency

Vitamin B<sub>12</sub> deficiency is not generally considered to be a major problem in the tropics. However, there are some situations in which the recognition of vitamin B<sub>12</sub> deficiency is important. These include areas where veganism is common for religious or other reasons, because vitamin B<sub>12</sub> is found only in food from animal sources. Vitamin B<sub>12</sub> deficiency may also occur in abdominal tuberculosis when the terminal ileum is involved and leads to malabsorption. Pernicious anemia is said to be rare in tropical countries, especially in the Indian subcontinent. There are no major systematic studies of pernicious anemia in Africa, but there are numerous case reports that suggest that the condition may occur at a much earlier age than in northern Europe, where the youngest patient recorded was 16 years of age.<sup>28</sup>

Deficiency of vitamin B<sub>12</sub> can lead to a megaloblastic anemia, symmetrical polyneuropathy, and, less frequently, gonadal dysfunction and glossitis. Subacute degeneration of the cord may ensue if the deficiency is not treated. The combination of anemia and neurological symptoms should alert the physician to the possibility of pernicious anemia.

### Anemia of Chronic Disease

ACD describes a normocytic anemia or sometimes a mildly to moderately microcytic, hypochromic anemia that occurs in patients with infectious, inflammatory, or neoplastic disease.<sup>3,29-31</sup> The important causes of ACD in the tropics include acute infections such as pneumonia or septicemia, chronic infections such as tuberculosis and HIV infection, and only rarely autoimmune disorders such as rheumatoid arthritis and systemic lupus erythematosus.

### Pathogenesis

ACD is characterized by underproduction of RBCs; the reticulocyte count is usually low. The bone marrow is either normocellular or initially hypocellular, but occasionally it can be hypercellular due to increased granulocytic activity (see Table 131-2). The pathogenesis of ACD is complex; the main mechanism appears to be a block in the incorporation of iron into erythroblasts with an increase in macrophage iron possibly due to the release of proinflammatory cytokines.<sup>3</sup> These include interleukin (IL)-1, IL-6; interferons- $\alpha$ , - $\beta$ , and - $\gamma$ ; and

tumor necrosis factor- $\alpha$ . ACD can lead to diagnostic difficulties, especially when there is coexistent iron deficiency.

### Management

ACD resolves after successful treatment of the underlying condition. In untreatable conditions or where there is limited response to treatment or in the initial phases of treatment, other approaches can be used to alleviate the anemia, such as blood transfusion. Despite low serum iron, administration of iron is of limited or no benefit. ACD has been shown to respond to administration of recombinant erythropoietin,<sup>30</sup> but this treatment is less likely to be available where resources are limited.

### Inherited Red Blood Cell Disorders

There is a high prevalence of genetic disorders affecting RBCs in tropical areas where malaria is or has been endemic. It is thought that carriers of these disorders are protected against malaria even though people fully affected may suffer severe consequences if they contract malaria. The malaria hypothesis proposes that the protective benefit from the carrier state leads to a better survival advantage than either the normal or affected homozygote.

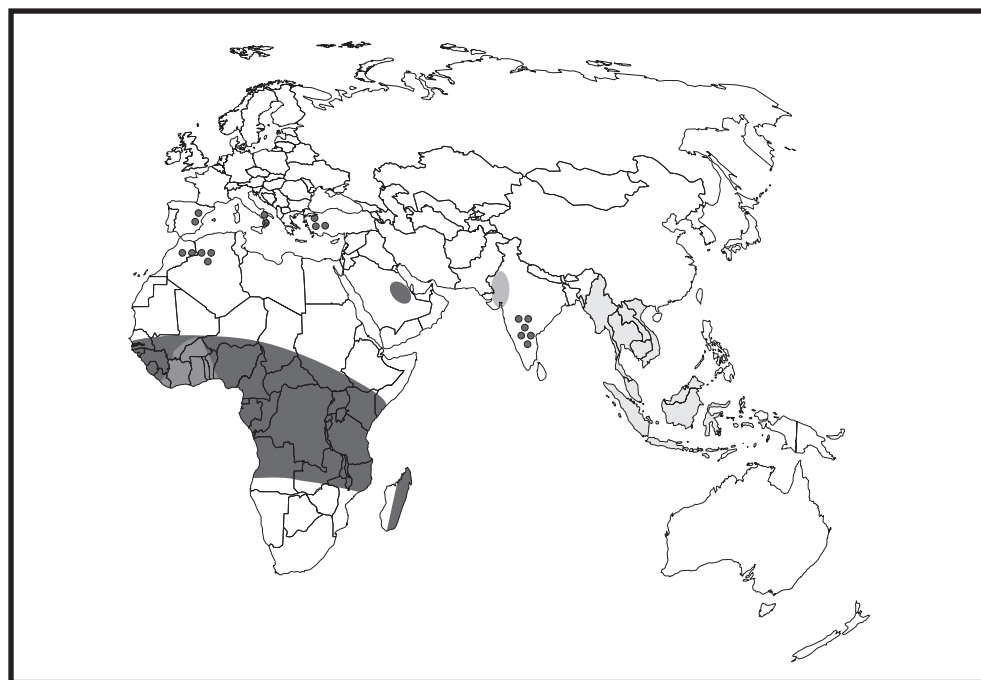

The majority of these disorders lead to hemolytic anemia in affected people, either in the steady state or under conditions

of stress. The most important of these disorders are the sickling disorders, the thalassemia syndromes, and G6PD deficiency.

### Sickling Disorders

SCA is a major cause of morbidity and mortality in children in rural Africa, where the condition is common.<sup>32–34</sup> A single DNA base substitution leads to an amino acid substitution from valine to glutamic acid in position 6 of the  $\beta$  globin chain. This substitution causes a major change in the solubility of Hb S under conditions of low oxygenation, leading to the formation of “tactoids”—elongated crystalline structures that lead to the formation of classic sickle cells, which can lead to irreversible RBC sickling. SCA occurs when the condition is inherited in the homozygous state. The precipitating factors for sickling episodes include infections, hypoxia, and dehydration, but in many patients there may not be an obvious precipitating cause. At birth, the amount of Hb S is too low to cause problems because the predominant Hb is Hb F.

Other sickling disorders include the coinheritance of Hb S with  $\beta^+$ - or  $\beta^0$ -thalassemia (i.e., Hb S  $\beta$ -thalassemia) or Hb C trait (Hb SC) or Hb D (Hb SD). These cases may be milder than SCA. There is thus major variability in the clinical picture in sickling disorders from individual to individual due to the interaction of a variety of genotypes, the level of Hb F, interaction with  $\alpha$ -thalassemia, unknown genetic factors, and

#### Hemoglobinopathies

- Hb S
- Hb S, sporadic cases
- Hb C
- Hb D
- Hb E

environmental factors (e.g., altitude). It is thought that the gene arose on four independent genetic backgrounds, as shown by the variety of  $\beta$ -globulin haplotypes. The effects of the sickle Hb from these haplotypes are similar, although inheritance of certain haplotypes may be associated with mild clinical disease.

The first manifestation of the disease usually occurs after 6 months of life, when the most common presentation is that of a dactylitis (Box 131-3). As the child grows older, other manifestations include painful crises due to vascular occlusion in bone and sometimes other organs, such as the brain, gastrointestinal tract, and lung. The typical crisis that occurs is due to multiple microinfarcts in bone leading to severe disabling pain. More serious complications include sequestration crises in the lungs, spleen, or, less commonly, the brain, ranging

from minor strokes to repeated infarcts and major cerebral infarcts. In rural areas, children frequently die at an early age from SCA, often from malaria or sepsis, but with careful medical attention they may survive to adulthood. Patients with SCA are especially susceptible to infection with *Streptococcus pneumoniae* and *Salmonella* spp. Patients with sickle cell trait (Hb S) are not anemic and rarely symptomatic, except when they have painful crises in unphysiologic conditions such as in unpressurized aircraft and during anesthesia.

**Management.** In general, treatment of acute crises involves ensuring adequate hydration, oxygenation, and analgesia; vigorous treatment of the underlying infection; keeping patients warm in cold weather; and reversal of acidosis. More severe complications, such as acute anemia due to splenic sequestration, increased hemolysis, parvovirus infection, or lung sequestration, are treated with top-up transfusion when the Hb falls below 6 g/dL. Where the Hb is higher and in the presence of certain complications, such as chest syndrome, priapism, and severe abdominal sickling, exchange transfusions are advocated to reduce the Hb S percentage to less than 20% and to continue by monthly transfusion thereafter. Pain management is particularly important. The pain is often very severe and may necessitate the use of opiate analgesia at frequent intervals. The particular opiate used (e.g., pethidine, diamorphine, or morphine) is dependent on local preference. Opiates have the disadvantage of a depressive effect on respiratory drive, which may worsen existing hypoxia, and potential addiction in those requiring opiates for repeated attacks. A study in Jamaica showed that, using pulse oximetry, a considerable degree of hypoxia may be found in patients with sickling disorders in the steady state.<sup>35</sup> Nonsteroidal anti-inflammatory drugs may be useful for bone pain provided there are no contraindications to their use.

**Prevention of Complications.** Prevention of the complications of SCA rests on the recognition and avoidance of precipitating factors of acute attacks, such as exposure to cold (e.g., swimming), dehydration, infections, altitude, travel in nonpressurized aircraft, anesthesia, and extremes of physical activity. Parents and patients should be taught to recognize early the manifestations of disease, such as dactylitis or splenic sequestration, which may begin with symptoms of listlessness and signs of pallor. Because these patients have effectively been autosplenectomized, they should receive pneumococcal, *Haemophilus influenzae* type b (Hib), and meningococcal vaccinations as well as prophylactic antimalarials, impregnated bed nets, and early treatment of malaria. Hepatitis B vaccination should be considered, especially when patients require transfusion and donors are not screened. Folate 5 mg/day should also be given because of the high RBC turnover.

Hydroxycarbamide (previously known as hydroxyurea) reduces the frequency of painful crisis, chest syndrome, and transfusion requirements in both adults and children with severe sickle cell disease. It also appears to improve growth and possibly prevent hyposplenism in children. It has not been proven to prevent stroke or avascular necrosis in joints, and it is the subject of ongoing trials in Europe and North America.<sup>36</sup> Caution is advised, however, because its long-term profile in terms of toxicity, mutagenicity, teratogenicity, and leukemogenic potential is unknown. Careful discussion of these issues with patients prior to commencing hydroxyurea is essential. For guidelines on the use of hydroxyurea in sickle cell disease, see Box 131-4.

### Box 131-3 Clinical Manifestations of Sickle Cell Anemia

#### **Bone Marrow and Bone**

Expansion of hematopoiesis leading to  
Dactylitis (hand and foot syndrome), especially at 4 to 6 months of age  
Prognathism  
Bossing of the skull  
Chronic hemolytic anemia  
Painful crises due to microinfarction of bone  
Osteomyelitis, often due to *Salmonella* spp.

#### **Lungs**

Acute chest syndrome with breathlessness, reduced oxygen saturation (<70%), and radiographic changes  
Lung infections often complicated; if hypoxia results, this may precipitate a crisis  
Ultimately may lead to pulmonary fibrosis and cor pulmonale

#### **Heart**

Cardiomegaly due to chronic anemia  
Congestive cardiac failure in later life

#### **Spleen**

Hypoactivity leading to susceptibility to infection, including encapsulated organisms and malaria  
Acute sequestration crisis with rapid enlargement and anemia, especially in infancy, and which tends to recur  
Chronic splenic enlargement with hypersplenism (anemia, leukopenia, and thrombocytopenia)

#### **Liver and Gallbladder**

Acute liver sequestration  
Gallstones

#### **Kidneys**

Renal tubular defect leads to inability to concentrate urine, leading to enuresis  
Dehydration, which may precipitate crises  
Tubular necrosis  
Intermittent hematuria  
Chronic renal failure

#### **Brain**

Recurrent cerebral infarction (may be silent)  
Stroke

#### **Skin**

Chronic leg ulcers (seen especially in Jamaica)

**Box 131-4** Hydroxycarbamide (Hydroxyurea) in Sickle Cell Disease**Patient Exclusion Criteria**

Regular transfusion regime  
 Abnormal liver function tests (AST or ALT >2× upper limit of normal)  
 Inability to attend clinic regularly for follow-up

**Patient Eligibility**

Patients (Hb SS or Sβ<sup>0</sup>-thalassemia, not Hb SC) with a severe clinical course may be offered hydroxyurea, i.e., with  
 Three admissions with painful crisis within 1 year, or  
 Frequent days of pain at home, leading to a lot of time off work, or

Recurrent acute chest syndrome

The following predict a more severe clinical course and are additional reasons to consider offering hydroxyurea:

Steady-state values

Hb < 7 g/dL

WBC > 15 × 10<sup>9</sup>/L

HbF < 6%

Renal insufficiency due to sickle cell disease

**Dose and Monitoring**

Start at 15 mg/kg/day (to the nearest 500 mg/day). If no or poor response, increase dose by increments of 5 mg/kg/day every 4 weeks (max: 30 mg/kg/day)

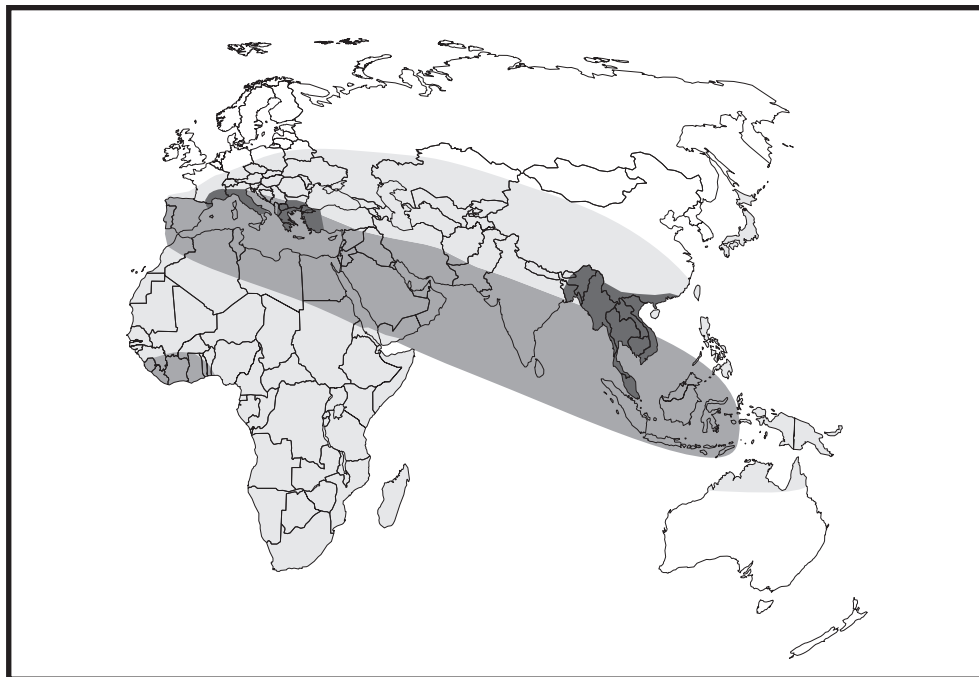

Monitor FBC, Hb F %, and reticulocytes every 1 or 2 weeks initially, then every 4 weeks when on a stable dose

Monitor biochemistry profile (hydroxyurea has renal excretion and hepatic toxicity)

**Thalassemia Syndromes**

The thalassemias are a group of disorders in which there is reduced production of one of the two main types of globin chains,  $\alpha$  or  $\beta$ , leading to  $\alpha$ - or  $\beta$ -thalassemia, respectively. These conditions are widely distributed throughout areas of Africa, the Mediterranean, the Middle East, the Indian subcontinent, and Southeast Asia.  $\beta$ -Thalassemia is especially common in the tropics in areas such as northern Thailand, Laos, and Vietnam. In these areas, there are complex interactions between these disorders and Hb E, a  $\beta$ -chain variant that is also underexpressed leading to a thalassemia-like phenotype. In Africa,  $\beta$ -thalassemia occurs in the northern areas of West African countries such as Ghana.

The underlying molecular genetic abnormalities of these disorders are complex. Each normal individual has four functioning  $\alpha$  genes and two  $\beta$  genes. In  $\alpha$ -thalassemia, one, two, or three of the  $\alpha$  globin genes may be nonfunctional. Deletion of a single gene in one chromosome is labeled  $\alpha^+$  thalassemia and of two on the same chromosome as  $\alpha^0$ . Homozygotes for  $\alpha^0$  (deletion of all four genes) lead to intrauterine or neonatal death from hydrops fetalis. In Hb H disease,  $\alpha^0/\alpha^+$  double heterozygotes, three of the  $\alpha$  globin genes are nonfunctional. In  $\beta$ -thalassemia, output from each  $\beta$  globin allele may be reduced ( $\beta^+$ ) or absent ( $\beta^0$ ). The underproduction of Hb leads to microcytic, hypochromic RBCs. Globin chain imbalance results in the formation of tetramers of  $\beta$  chain (Hb H) in  $\alpha$ -thalassemia or  $\gamma$  chain (Bart's Hb) in the fetus and neonate. In addition to microcytosis, anemia is made worse by ineffective erythropoiesis because of globin chain imbalance in  $\beta$ -thalassemia and by hemolysis in Hb H disease since Hb H is unstable.

**Thalassemias**

■  $\alpha$ -Thalassemia, two  $\alpha$  gene deletions ( $\alpha^0/\alpha^0$ )

■  $\beta$ -Thalassemia

■  $\alpha$ -Thalassemia, single  $\alpha$  gene deletion ( $\alpha^+/\alpha^+$ )

Underexpression of  $\alpha$  chains in  $\alpha$ -thalassemia is commonly caused by deletions involving one or more of the  $\alpha$  genes (two on each chromosome 16) but sometimes also involving gene expression control regions. In contrast, the majority of  $\beta$  chain defects are caused by single base pair mutations usually resulting in reduced or absent gene expression ( $\beta^+$ - or  $\beta^0$ -thalassemia) from the single  $\beta$  gene on each chromosome 11. Whatever the cause, underproduction of adult Hb leads to the formation of hypochromic, microcytic RBCs with reduced MCH. The other main thalassemic indices include an elevated RBC count, a low MCV and MCH, and a relatively less reduced MCHC.

Clinically, the thalassemias may be grouped into three entities—minor, intermedia, and major:

1. In thalassemia minor, there is only a minor degree of hypochromic anemia (Hb 9 to 11 g/dL) in the absence of physiologic stress. Some patients, however, may develop a more clinically significant anemia in certain circumstances, such as pregnancy or other physiologic stress. Subjects generally appear clinically normal. Examples are  $\alpha^+$  hetero- and homozygotes,  $\alpha^-$  heterozygotes,  $\beta$ -thalassemia trait, and the Hb A<sup>Constant spring</sup> heterozygote. Diagnosis is made on routine RBC count, most commonly because of the low MCV, which may be confused with iron deficiency (see Table 131-2).
2. In thalassemia intermedia, there is a moderate hypochromic, microcytic anemia but the patient is not normally transfusion dependent. Patients may become transfusion dependent intermittently when exposed to stress, such as pregnancy or intercurrent infection. Examples of thalassemia intermedia include Hb H disease and interaction between  $\beta^0$ -thalassemia and Hb E trait and between  $\beta^0$ - and  $\beta^+$ -thalassemia. Splenomegaly is a common feature in the thalassemia intermedia syndrome and hypersplenism may complicate the clinical picture. Patients may have cardiomegaly and in later life suffer from cardiac failure. Even in the absence of transfusion, iron overload may result from increased dietary iron absorption because of the increased erythropoiesis.
3. In thalassemia major ( $\beta^0$  homozygotes) there is little or no production of Hb A, and there is progressive anemia from a few months of age leading to an Hb of less than 4 g/dL in the absence of transfusion. In untreated or inadequately treated patients, there is an expansion of erythropoiesis causing expansion of medullary bone, leading to features such as prognathism and bossing of the skull as well as hepatosplenomegaly. There is severe growth retardation and pathologic fractures. In untreated cases, death may occur in the first few years of life. Patients who are transfused may survive longer but develop iron overload with hypogonadism and secondary deposition of iron in the myocardium, pancreas, and liver, leading to death due to cardiac failure, diabetes mellitus, or liver failure, unless intensive iron chelation is used.

**Management.** The cornerstones of management are as follows:

1. *Counseling and advice:* In thalassemia trait the main clinical problems are the differential diagnosis from iron deficiency to avoid unnecessary and potentially harmful

iron therapy and provision of proper counseling regarding prevention of pregnancy with a thalassemia major child.

2. *Transfusion:* In Hb H disease, a chronic hemolytic state, episodes of acute hemolysis may occur, necessitating transfusion. In the case of thalassemia intermedia, monitoring is required perhaps at 6-month intervals in childhood and yearly intervals in adult life,<sup>37</sup> and transfusion may be needed during periods of stress. In thalassemia major, regular transfusions to maintain an Hb higher than 10 g/dL are needed from an early age to maintain normal growth and prevent bony deformities. However, repeated transfusion carries the risk of iron overload, sensitization to white blood cells causing febrile reactions, and the possibility of transmission of infections such as hepatitis B and C and HIV.
3. *Iron chelation with subcutaneous desferrioxamine infusion together with vitamin C:* Continuous iron chelation is also needed to prevent cardiac, hepatic, and endocrine organ deposition of iron leading to dysfunction of these organs and ultimately death. This treatment regimen, in addition to being expensive, requires special motivation for effective compliance.
4. *Splenectomy:* Some patients with either thalassemia intermedia or thalassemia major may develop hypersplenism consisting of splenic enlargement accompanied by increasing anemia, leukopenia, and thrombocytopenia. These patients may require splenectomy. Indications for splenectomy include a requirement for transfusion in a patient who previously did not require transfusion, increasing transfusion requirements in those who are transfusion dependent, clinically significant thrombocytopenia, and the mechanical effects of the large spleen. However, splenectomy should be considered carefully in a tropical environment.
5. Some patients may develop cardiomegaly with compromised myocardial function leading to cardiac failure in the fifth or sixth decade of life. Monitoring with chest radiography in the first instance and echocardiography, if available, may be helpful. Such patients may require transfusion.

### Glucose-6-Phosphate Dehydrogenase Deficiency

All cells of the body contain G6PD, an enzyme that catalyzes the breakdown of glucose-6-phosphate to 6-phosphogluconate producing reduced NADPH from oxidized NADP and leading to the five-carbon sugar ribose necessary for nucleotide synthesis. Reduced NADPH is essential to maintaining several intracellular protein and membrane sulfhydryl groups in their reduced state (e.g., glutathione). The RBC is particularly susceptible to the deleterious effect of oxidant stress because of its function in oxygen carriage, and for this reason the effects of enzyme deficiency leading to hemolysis are most commonly observed in red cells.<sup>38</sup>

G6PD deficiency is sex linked and affects mainly males. The enzyme is a protein consisting of 515 amino acids and has a molecular weight of 59 kDa. There are many variants of G6PD, and the majority of these are the result of a single base mutation in the genes causing a single amino acid substitution. The substitution may have no or a minor effect on the function

**Table 131-3** Examples of the Most Common Glucose-6-Phosphate Dehydrogenase (G6PD) Variants

Type	Characteristics	G6PD Activity (%)	Distribution
B	Slower electrophoretic mobility than A	100	Common wild type worldwide
A	Faster electrophoretic mobility than B	70–90	Africa
Deficient variants			
A <sup>−</sup>	Drug and infection induced; hemolysis self-limited	15–20	Africa
Mediterranean	Severe, sometimes fatal hemolysis	<10	Mediterranean
Mahidol	Severe hemolysis	<10	Thailand, Southeast Asia
Canton	Severe hemolysis	<10	Orientals

of the enzyme, producing functionally normal variants, or may have a moderate or severe effect. Using previously agreed WHO methodology, including electrophoretic mobility, kinetics, and other properties, 299 variants of G6PD have been described but only a few are encountered frequently in clinical practice (Table 131-3). Using more specific DNA characterization, 60 enzyme variants have been identified. Deficiency of G6PD is mostly seen in hemizygous males and less frequently in homozygous females. The gene frequency of G6PD mutations is particularly high in certain populations, such as Kurdish Jews (0.70) and black Americans (0.1 to 0.11), black Africans, and some Asians.

### Clinical Picture

G6PD deficiency may present with a wide spectrum of clinical manifestations. The generally accepted broad classification is as follows: class 1, the most severe, characterized by a chronic nonspherocytic hemolytic anemia; class 2 deficiency, such as G6PD Mediterranean (Gd Med), in which there is significant hemolysis with exposure to oxidants; and class 3, in which there is only mild to moderate deficiency, such as Gd A<sup>−</sup> found in Africa. Class 1 variants are rare and usually not found as a polymorphism in areas where malaria is endemic. In contrast, class 2 and 3 variants are common in malaria-endemic areas. The following are the most common manifestations of G6PD deficiency:

- **Infection-induced hemolysis:** This is one of the most common manifestations of G6PD deficiency observed in tropical areas and is seen in conditions such as viral hepatitis, typhoid, malaria, lobar pneumonia, and severe sepsis in which the release of oxygen radicals and nitric oxide may lead to hemolysis. Patients with G6PD deficiency are more likely to develop intravascular hemolysis mimicking blackwater fever with falciparum malaria. The hemolysis seen in G6PD deficiency with viral hepatitis is unexplained.
- **Drug-induced hemolysis:** The range of drugs causing hemolysis in the tropics in G6PD-deficient people may be more limited because of the milder forms of deficiency present in these areas.<sup>38</sup> The issue of antimalarial drugs is important. The schizonticidal drugs chloroquine and quinine are considered safe in normal therapeutic doses. The combination drugs containing sulfonamide, dapsone, or pyrimethamine should be avoided; dapsone may cause hemolysis even in non-G6PD-deficient

subjects. Primaquine is one of the major drugs that should be avoided. The manufacturers of the aminoquinoline drugs, such as ciprofloxacin and ofloxacin, advise caution in their use in G6PD deficiency.

- **Neonatal jaundice:** This is a common and potentially serious complication of G6PD deficiency in Asia, Greece, and Africa that can lead to kernicterus. Anemia is not always present and may be due to hepatocyte rather than RBC deficiency of the enzyme. A history of neonatal jaundice may assist in the diagnosis of G6PD deficiency in later life.
- **Food-induced jaundice:** Some foods and additives are known to contain oxidants that may cause hemolysis in G6PD deficiency. The best known of these are fava beans and a food coloring in Nigeria called *suya*. Favism is a hemolytic anemia associated with the ingestion of fava beans seen mainly in G6PD deficiency but which will vary according to the type of bean, the way the beans are cooked, whether the beans are dried or fresh, and the metabolism of the individual.

### Diagnosis

The blood film is normal in patients with G6PD deficiency in the steady state. However, during a hemolytic crisis changes may be seen in the peripheral blood, including irregularly contracted RBCs called “hemighosts” (Plate 131-1A). In cases in which there is overwhelming hemolysis or in patients who are hyposplenic, a supravital stain will reveal the presence of Heinz bodies, which are denatured Hb or globin precipitates associated with red cell membrane (Plate 131-1B).

There are several methods available commercially for the detection of G6PD deficiency; all utilize the reduction of NADP to NADPH in the presence of excess G6PD and red cell lysate. Reduced NADPH is then detected either by fluorescence under ultraviolet light or by an electron transfer reaction involving tetrazolium compounds that are reduced by NADPH to insoluble forms.

G6PD deficiency of all types can be detected easily in this manner in male hemizygotes in the steady state and in homozygotes with the more severe class of enzyme deficiencies (e.g., Gd Med). Difficulties may arise in the less severe types of deficiencies (class 3, especially Gd A minus [A<sup>−</sup>]), in which reticulocytes and young RBCs, relatively rich in enzymes, tend to restore levels to the normal range. This relatively normal G6PD level in otherwise deficient people explains why these

milder deficiencies cause self-limited hemolysis even in the presence of continued use of the drug or infection. Diagnosis of heterozygotes is more problematic. An intermediate range in the enzyme assay may be diagnostic of heterozygosity in females, but a considerable number of females will fall within the normal range. Genetic studies using DNA analysis are being increasingly used to diagnose G6PD deficiency and the carrier state, but they are not routinely available in the tropics.

## Management

Acute management of G6PD deficiency during a hemolytic crisis includes adequate hydration, maintenance of urinary output, withdrawal of the offending drug or agent responsible for the hemolysis, and transfusion of RBCs if necessary. In neonatal jaundice, phototherapy or exchange transfusions may be required according to bilirubin levels. Deficient patients should be counseled to (1) avoid agents that are potentially hemolytic; (2) report early for treatment in case of infections, especially infections in children; and (3) report the onset of jaundice or pallor early, especially in children.

# Sexually Transmitted and Urinary Tract Infections

ARLENE C. SEÑA  
ALLAN RONALD  
KIMBERLEY K. FOX  
MYRON S. COHEN

## INTRODUCTION

Sexually transmitted infections (STIs) are a major global public health problem; they are responsible for serious and sometimes fatal complications, and facilitate the transmission of the human immunodeficiency virus (HIV). Approximately 340 million new cases of the five curable STIs—gonorrhea, chlamydia, syphilis, chancroid, and trichomoniasis—were estimated to have occurred worldwide in 1999.<sup>1</sup> In the developing world, it is estimated that STIs, excluding acquired immunodeficiency syndrome (AIDS), are the second leading cause of healthy life lost among women between 15 and 44 years of age.<sup>2</sup> With the continued epidemic of HIV/AIDS, the control of other STIs has gained greater significance due to the established links between STIs and HIV transmission.

Though South and Southeast Asia had the largest number of new cases of STIs estimated in 1999, sub-Saharan Africa had the highest STI prevalence among the developing regions (119 cases per 1000 population).<sup>1</sup> The reliability and completeness of STI data from developing countries are inconsistent due to lack of surveillance systems and the extent of asymptomatic infections in the population, which are usually not detected or reported. Trichomoniasis continues to be the most common STI worldwide, with an estimated 76 million new cases in South and Southeast Asia in 1999.<sup>1</sup> However, the prevalence of herpes simplex virus type 2 (HSV-2) is increasing and is now the major cause of genital ulcer disease (GUD) throughout the world. High rates of HSV-2 are seen in sub-Saharan Africa and the Caribbean, with serological prevalences over 50% reported among adults from Kenya, Zambia, and Cameroon.<sup>3</sup>

Many ecological and behavioral factors contribute to the epidemic of STIs. Factors which vary widely among societies include male circumcision traditions, condom use, spermicide and other contraception practices, and patterns of alcohol or

illicit drug use that influence sexual behaviors.<sup>4</sup> Factors contributing to the high rate of STIs in the tropics include changes in population density (e.g., urbanization); stages of demographic transition (e.g., a high proportion of young people at risk); migration and travel (e.g., increased mobility); and the accessibility, quality, and use of STI health services (e.g., inadequate health facilities).

Contact with sex workers is an important risk factor for STI acquisition and is reported as the probable source of infection by 40% to 80% of male patients in Africa.<sup>5,6</sup> Other STI risk factors include young age, unmarried status, residence in an urban area, multiple sexual partners, and a history of prior STIs.<sup>7</sup> Several STI-related syndromes are caused by a multitude of viruses and bacteria (Table 132-1). Complications of STIs such as pelvic inflammatory disease (PID), ectopic pregnancy, infertility, epididymitis, urethral strictures, neonatal conjunctivitis, and congenital syphilis occur frequently in tropical settings, presumably in part due to the lack of effective diagnostic and therapeutic interventions. In the absence of screening programs, the extent of asymptomatic disease associated with most STIs contributes to delays in diagnosis and treatment. Complications may be especially common in patients coinfecting with HIV/AIDS.

Utilization of standardized protocols adapted to local epidemiological and antimicrobial susceptibilities of organisms is generally recommended in STI management. Treatment of STIs based on laboratory diagnosis is theoretically desirable, but is neither necessary nor possible in most settings. Therefore, algorithms (also called flowcharts or decision trees) have been developed as guides for STI management based on clinical signs and symptoms.<sup>8-10</sup> Promoted by the World Health Organization (WHO), the syndromic approach allows health-care providers to manage STIs without determining etiology with laboratory tests or specialized techniques. The advantages of syndromic management are the immediate treatment of patients and avoidance of laboratory costs. These must be balanced against the disadvantages, which include failure to detect atypical or subclinical infections, and the costs and risks associated with treatment of uninfected persons.<sup>11</sup> Flowcharts for the management of STI syndromes in men and PID and genital ulcers in women have proven diagnostic validity in various clinical settings; however, flowcharts for the management of vaginal discharge tend to have low sensitivity and specificity in clinically differentiating between cervical and vaginal infections.<sup>9,10,12,13</sup> These algorithms can be improved with a risk profile approach whereby selected symptoms and signs, as well as demographic and behavioral characteristics, are chosen for their likelihood of association with the STI under consideration.<sup>10</sup>

Urinary tract infections (UTIs) can have similar clinical presentations to STIs. The global incidence of UTIs exceeds 150 million annually and these infections are common everywhere. The epidemiology of UTI in developing countries has not been well studied, and extrapolation from studies in industrialized societies is required to estimate the extent and burden of illness. UTIs are categorized as either “uncomplicated,” when they occur in a normal urinary tract with no structural, functional, or underlying host illness to account for the infection, or “complicated,” when an underlying abnormality is believed to have enabled the infection to occur.

**Table 132-1** Common Sexually Transmitted Infection-Related Syndromes and Etiologic Agents

Syndrome	Major Etiologic Agents
Genital ulcer disease	
Chancroid	<i>Haemophilus ducreyi</i>
Syphilis	<i>Treponema pallidum</i>
Genital herpes	Herpes simplex virus
Granuloma inguinale	<i>Calymmatobacterium granulomatis</i>
Lymphogranuloma venereum	<i>Chlamydia trachomatis</i> (L serovars)
Nonulcerative genital lesions	
Genital warts	Human papillomavirus
Molluscum contagiosum	Molluscum virus
Scabies	<i>Sarcoptes scabiei</i>
Pediculosis*	<i>Phthirus pubis</i>
Vaginal discharge	
Vaginitis	<i>Trichomonas vaginalis</i> , <i>Candida albicans</i>
Bacteria vaginosis	<i>Gardnerella vaginalis</i> , <i>Mycoplasma hominis</i> , peptostreptococci, <i>Bacteroides</i> species, <i>Mobiluncus</i> species
Endocervicitis	<i>Neisseria gonorrhoeae</i> , <i>Chlamydia trachomatis</i> , herpes simplex virus
Endocervicitis	<i>Trichomonas vaginalis</i> , herpes simplex virus
Urethritis (women)	<i>Neisseria gonorrhoeae</i> , <i>Chlamydia trachomatis</i>
Urethritis (men)	<i>Neisseria gonorrhoeae</i> , <i>Chlamydia trachomatis</i> , <i>Ureaplasma urealyticum</i> , <i>Mycoplasma genitalium</i> , <i>Trichomonas vaginalis</i> , herpes simplex virus
Pelvic inflammatory disease	<i>Neisseria gonorrhoeae</i> , <i>Chlamydia trachomatis</i> , <i>Mycoplasma hominis</i> , <i>Mycoplasma genitalium</i> , anaerobic bacteria
Epididymitis	<i>Neisseria gonorrhoeae</i> , <i>Chlamydia trachomatis</i>
Proctitis	<i>Neisseria gonorrhoeae</i> , <i>Chlamydia trachomatis</i> , herpes simplex virus
Pharyngitis	<i>Neisseria gonorrhoeae</i> , <i>Chlamydia trachomatis</i>
Conjunctivitis	<i>Neisseria gonorrhoeae</i> , <i>Chlamydia trachomatis</i> (including L serovars)
Hepatitis	Hepatitis A virus, hepatitis B virus, hepatitis C virus, cytomegalovirus

\*Pediculosis (pubic lice infestation) may be mistaken for genital lesions.

## GENITAL ULCERS

GUD occurs more frequently in tropical countries than in other areas of the world, accounting for 10% to 30% of STI clinic visits in Asia and Africa compared with 2% to 5% in western Europe and North America.<sup>14</sup> The STIs resulting in GUD include chancroid, syphilis, genital herpes, granuloma inguinale or donovanosis, and lymphogranuloma venereum (LGV). The male-to-female ratio for GUD in tropical areas is at least 4:1.<sup>15</sup> This may be due to the greater visibility of the male genitalia, resulting in a higher rate of diagnosis in men, or prostitution, resulting in a higher number of cases in men. *Haemophilus ducreyi* has traditionally been the most common cause of GUD in the tropics, previously reported among 60% to 70% of genital ulcers in men,<sup>16</sup> and 50% of genital ulcers in women.<sup>17</sup> The increasing prevalence of HSV-2 in developing countries, including South Africa, Peru, and the Dominican Republic, has now made genital herpes the most common cause of GUD worldwide.<sup>3,18,19</sup> Granuloma inguinale occurs most frequently in western Papua New Guinea, India, the Caribbean, and among Australian aborigines.<sup>20,21</sup> LGV is endemic in parts of Africa, India, Asia, South America, and the Caribbean. Though only 10% of cases of LGV are noted to have a primary lesion at the time of the initial presentation, this disease should be included in the differential diagnosis of GUD.

GUD usually begins as a papule or pustule on the skin or mucous membranes, followed by ulceration and development of inguinal and/or femoral lymphadenopathy. *Treponema pallidum*

penetrates through either abraded skin or intact mucous membranes within hours to days after exposure, subsequently enters the bloodstream, and disseminates.<sup>22</sup> HSV enters the epidermis and dermis, followed by replication in nerve ganglia and migration via peripheral sensory nerves, potentially (but rarely) leading to development of lesions distant from the primary site of exposure.<sup>23</sup> The other bacterial STIs that cause GUD typically result in localized disease; disseminated disease is rare but has been reported with donovanosis.

## Clinical Manifestations

The manifestations of STIs associated with GUD are outlined in Table 132-2. The clinical features may help differentiate GUD etiology. Chancroid is the most likely disease in a patient presenting with one or more painful genital ulcers accompanied by an inguinal bubo (a group of tender, matted lymph nodes). The pain associated with the ulcer is perhaps the most distinguishing feature of this disease. The ulcers have ragged, undermined borders, a purulent base, and no induration; they may coalesce to form giant lesions. They are most frequently located on the coronal sulcus and prepuce in circumcised and uncircumcised men, respectively. In men, painful inguinal lymphadenopathy occurs in over half of patients; it occurs less commonly in women. The lymphadenitis of chancroid is usually unilateral; the bubo can become fluctuant and rupture, resulting in a draining abscess.

**Table 132-2** Typical Clinical Features in the Differential Diagnosis of Genital Ulcer Disease Caused by Sexually Transmitted Infections

Feature	Chancroid	Primary Syphilis	Genital Herpes	Granuloma Inguinale	Lymphogranuloma Venereum
Incubation period	3–7 days	2–4 weeks	2–7 days	1–4 weeks	10–14 days
Number of lesions	Usually 1–3	Usually 1	Multiple	Single or multiple	Usually 1
Genital lesion					
Appearance	Deep, defined or irregular ulcer	Defined ulcer	Superficial, grouped vesicles or ulcerations	Defined or irregular ulcer; hypertrophic or verrucous	Papule, pustule, vesicle, or ulcer (transient)
Base	Yellow-gray, rough	Red, smooth, shiny	Red, smooth	Red, beefy, rough, usually friable	Variable
Induration	Soft	Firm	None	Firm	None
Pain	Common	None	Common*	Rare	Variable
Inguinal lymphadenopathy	Unilateral or bilateral; tender; may suppurate	Unilateral or bilateral; nontender; no suppuration	Bilateral; tender*	None; inguinal swelling	Unilateral or bilateral; tender, may suppurate
Constitutional symptoms	Rare	Rare	Common	Rare	Frequent

\*Occurs more commonly in primary episodes of genital herpes than in recurrences.

In comparison, a patient presenting with a painless solitary ulcer accompanied by nontender unilateral or bilateral inguinal lymphadenopathy most likely has primary syphilis. The ulcer is typically indurated with a defined, raised border, a clear, granular base, and a serous exudate. Though a solitary painless chancre is the hallmark of primary syphilis, almost half of patients have more than one lesion.<sup>24</sup> Syphilitic chancres are most frequently located on the inner or outer side of the foreskin or coronal sulcus in men, and the labia in women. As many as 10% of primary chancres may be extragenital.<sup>24</sup> Approximately one-third of homosexual men with primary syphilis will present with an anorectal lesion. Patients with secondary syphilis may also present with anogenital ulcers; however, these are usually accompanied by exanthema of the skin and mucous membranes.

A patient with grouped vesicles or ulcers on an erythematous base, especially with a history of similar episodes, has a high likelihood of having herpes. Genital herpes in the tropics is usually caused by HSV-2. A prodrome of paresthesias around the outbreak site usually precedes the appearance of lesions by 12 to 48 hours. The grouped vesicles are considered the hallmark of genital herpes; they subsequently rupture resulting in shallow, painful ulcerations with crusting. These lesions are usually located on the prepuce, the glans, and the shaft of the penis in men, and on the labia minora, labia majora, and cervix in women. The cervix may appear diffusely or locally erythematous, with superficial erosions and sometimes necrosis. Homosexual men may have lesions in the anorectal area, which may be accompanied with symptoms of proctitis. A patient with associated symptoms of low-grade fever, chills, malaise, tender bilateral lymphadenopathy, and severe pain or paresthesias is probably experiencing a primary first episode of genital herpes (e.g., there is no pre-existing antibody to HSV-1 or HSV-2). The duration of disease is

longer during primary infection. Vesicles can last 10 to 12 days before forming ulcers, which can persist for another 1 to 2 weeks. Symptoms tend to be milder during the nonprimary first episode of HSV infection, when there are pre-existing antibodies to the heterologous HSV type (in the tropics, over 90% of adults have had previous HSV-1 infection). Patients with recurrent disease, when detectable antibodies are present to the infecting HSV type, usually have fewer symptoms lasting no more than 10 days. Persistent, painful genital ulceration due to HSV-2 is extremely common in immunosuppressed HIV-infected patients in regions of high prevalence.

A patient with one or more nonpainful genital ulcers with inguinal swelling (pseudobubo) may have granuloma inguinale, also called donovanosis. This infection is caused by *Calymmatobacterium granulomatis*, a gram-negative bacillus. The patient may report the appearance of one or more firm, painless papules or nodules, which subsequently ulcerate. The predominant sites of involvement are the distal penis for men and the introitus for women; the inguinal area is affected in 10% of cases. Granuloma inguinale may take many forms, including an ulcerative or ulcero-granulomatous lesion (a nontender, beefy-red ulcer with a granulated base); a hypertrophic or verrucous lesion with profuse granulation and friability; a necrotic, painful lesion with a foul-smelling exudate; or a sclerotic bandlike lesion with fibrous tissue formation.

A patient with tender inguinal lymphadenopathy or a suppurating bubo without a visible genital ulcer may have LGV. This syndrome is caused by infection with the serovars L1, L2, and L3 of *Chlamydia trachomatis*. The lesion is transient and frequently goes unnoticed; it precedes the development of unilateral or bilateral lymphadenitis by 7 to 30 days. The lesion appears as a small, painless papule, pustule, or herpetiform ulcer. It is located most commonly on the coronal sulcus, prepuce, glans of the penis, or the urethral meatus in men,

and on the vulva, vaginal wall, or cervix in women. The most easily recognized clinical feature of LGV in men is the “groove sign,” or the enlargement of nodes above and below the inguinal ligament. However, a groove sign can also be found in patients with chancroid. The inguinal buboes of LGV may become fluctuant and rupture, or form a hard inguinal mass with suppuration. Women may present with enlarged pelvic nodes and associated pelvic pain, or with symptoms of proctitis due to lymphatic spread to the rectal mucosa.

## Diagnosis

The medical history should determine the suspected time of exposure, the nature and duration of the lesions, the presence of pain, and the presence of constitutional symptoms such as fever or malaise. The physical examination should include the skin, oral cavity, external genitalia, the inguinal or femoral lymph nodes, and the anorectal area. In women, a pelvic examination should be performed whenever possible.

The diagnosis of GUD can be problematic without laboratory testing, since several studies have demonstrated the unreliability of clinical etiologic diagnosis.<sup>25,26</sup> One study found that the clinical diagnosis of GUD was accurate in only 68% of cases where single infections were detected. The accuracy was highest (80%) for the most common etiology, chancroid, and least for other causes: 55% for primary syphilis, 27% for LGV, and

22% for genital herpes.<sup>26</sup> Diagnostic techniques for the specific agents associated with GUD are outlined in Table 132-3. Ideally, the diagnostic workup should include darkfield examination for *T. pallidum*, culture for *H. ducreyi*, culture for HSV, and serologic tests for syphilis. Cultures should be obtained from the base of the ulcer after washing the lesion with saline. If buboes are present, a diagnostic and therapeutic aspiration should be performed. Unfortunately, false negative tests are frequently encountered in the evaluation of GUD, due to the low sensitivity of available tests. Though darkfield microscopy can provide a definitive diagnosis of syphilis, a negative result does not exclude syphilis since the accuracy of the test depends on the quality of the specimen and the experience of the individual performing the procedure. Sufficient organisms may not be present following self-medication. Nontreponemal blood tests for syphilis, such as the rapid plasma reagin (RPR) test or the Venereal Disease Research Laboratory (VDRL) tests, are positive in approximately 80% of primary syphilis cases.<sup>27</sup> Furthermore, positive syphilis serologies may reflect past infection, and false positive results may occur for a variety of reasons. Confirmation with a specific treponemal test (fluorescent treponemal antibody absorption test or FTA-ABS; the microhemagglutinin assay—*T. pallidum* or MHA-TP; or the *T. pallidum* passive agglutination assay or TP-PA) is therefore important. The FTA-ABS has the highest sensitivity among the treponemal tests (86% to 100% for primary syphilis).<sup>27</sup>

**Table 132-3** Diagnostic Tests and Treatment for the Most Common Causes of Genital Ulcer Disease

	Definitive Diagnosis	Probable Diagnosis	Recommended Treatment Regimes
Chancroid	Culture	Clinical presentation	Azithromycin 1.0 g PO × 1; or ciprofloxacin 500 mg PO bid × 3 days; or erythromycin 500 mg PO tid or qid × 7 days (Alternative: ceftriaxone 250 mg IM × 1) (Pregnancy: erythromycin or ceftriaxone as above)
Primary syphilis	Darkfield examination; direct immunofluorescence	Clinical presentation; serology	Benzathine penicillin G 2.4 million units IM × 1 (Alternatives: procaine penicillin 1.2 million units IM × 10 days; or doxycycline 100 mg PO bid or tetracycline 500 mg PO qid × 14 days) (Pregnancy: penicillin as above)
Genital herpes	Viral culture	Clinical presentation; antigen detection by immunofluorescence or enzyme immunoassay; serology	Acyclovir 200 mg PO 5 ×/day, or acyclovir 400 mg PO tid, or famciclovir 250 mg PO tid, or valaciclovir 1.0 g PO bid × 7 days* (Pregnancy: oral acyclovir as above)
Granuloma inguinale	“Donovan bodies” in tissue smears or biopsy specimens	Clinical presentation	Azithromycin 1.0 g × 1, then 500 mg PO every day; or doxycycline 100 mg PO bid for a minimum of 14 days (Alternatives: erythromycin 500 mg PO qid, or tetracycline 500 mg PO qid, or trimethoprim (80 mg)–sulfamethoxazole (400 mg) 2 tablets PO bid for a minimum of 14 days) (Pregnancy: erythromycin as above)
Lymphogranuloma venereum	Isolation in cell culture	Clinical presentation; serology	Doxycycline 100 mg PO bid × 14 days; or erythromycin 500 mg PO qid × 14 days (Alternative: tetracycline 500 mg PO qid × 14 days) (Pregnancy: erythromycin as above)

\*Recommended for the primary episode of genital herpes. For recurrent genital herpes, the recommended regimens are acyclovir 800 mg PO bid × 5 days, famciclovir 125 mg PO bid × 5 days, valaciclovir 500 mg PO bid or 1.0 g PO daily × 5 days.

Other tests in the laboratory diagnosis of GUD have important limitations. The identification of gram-negative coccobacilli in parallel rows or in a clustered “school of fish” appearance is reported to be characteristic of *H. ducreyi*, but is no longer recommended due to its poor sensitivity and specificity. Culture for chancroid is considered to be the definitive test, but is difficult to perform and has an estimated sensitivity of 75% compared to nucleic acid amplification detection from genital ulcer swabs.<sup>14</sup> If a diagnosis of genital herpes is not certain from the clinical presentation, a culture can provide the most sensitive and specific test when available. The sensitivity of herpes culture approaches 100% for vesicular lesions, but decreases to 33% during the ulcer stage.<sup>28</sup> If the culture for HSV is not available, the Tzanck smear can provide a probable diagnosis of HSV; this is performed by scraping the base of the lesion, staining a slide of the material with Wright stain, and looking for multinucleated giant cells. The sensitivity of the Tzanck smear for genital herpes is approximately 67% in the vesicular stage and 50% in the ulcer stage.<sup>29</sup> Type-specific HSV serologies that detect antibodies to HSV glycoproteins have become available and can support a diagnosis of genital herpes in patients with atypical presentations.<sup>30</sup> When granuloma inguinale is suspected, a Giemsa stain or Wright stain of crushed tissue smears or biopsy specimens looking for Donovan bodies (bacillary organisms within histiocytes) should be performed. Donovan bodies can be demonstrated in only 60% to 80% of cases from either direct smears or biopsy specimens. The isolation of *C. trachomatis* in cell culture provides definitive diagnosis of LGV, but the recovery rate is only 50%.<sup>31</sup> Serologic testing with complement fixation (CF) or microimmunofluorescence (MIF) can assist the diagnosis when performed in the appropriate clinical setting, but does not distinguish among infections with other *Chlamydia* species. Positive titers greater than 1:256 with CF or greater than 1:128 with MIF are strongly indicative of LGV, although invasive genital infections with the *C. trachomatis* serovars D–K can also give rise to high serum titers.<sup>32</sup>

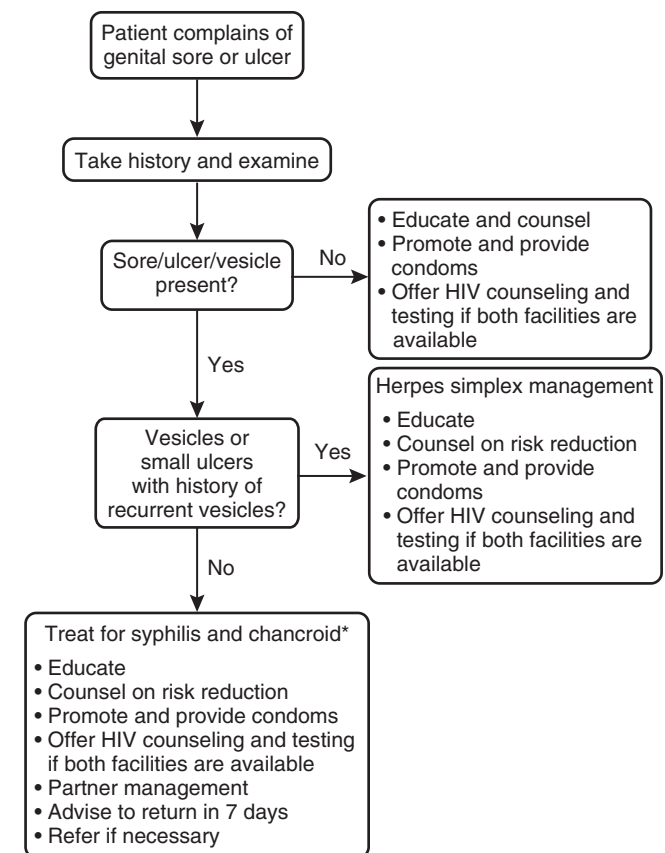

Coinfection with more than one pathogen has been reported in 5% to 10% of all GUD cases<sup>33</sup>; most commonly encountered are coexistent syphilis and chancroid. In one-fourth to one-half of GUD cases, no cause can be found by simple laboratory testing.<sup>13,33</sup> Nucleic acid amplification involving polymerase chain reaction (PCR) for *T. pallidum*, *H. ducreyi*, and HSV have been applied in research studies as a more sensitive detection method than traditional tests for the diagnosis of genital lesions.<sup>20,21,34,35</sup> Rapid diagnostic tests for *T. pallidum* are being investigated and may assist in future GUD diagnostic efforts by enabling immediate diagnosis at the first visit.<sup>36</sup>

Other causes of genital ulceration to consider in the differential include abrasions and trauma, contact dermatitis, fixed drug eruptions, Reiter's syndrome, Behçet's syndrome, and carcinoma. Infectious diseases such as systemic fungal diseases and cutaneous leishmaniasis, if endemic in the area, may also confuse the diagnosis. Atypical presentations of GUD associated with STIs must always be considered and are often seen in the tropics as a result of coinfections, coexistent HIV/AIDS, ineffective self-treatment, use of traditional remedies, superinfections, and other complications due to long-standing disease.

## Management

Algorithms for the management of genital ulcers depend on the local prevalence of causal agents. One example of an algorithm for the syndromic management of genital ulcers is the WHO flowchart provided in Figure 132-1. A similar algorithm whereby all patients with GUD were treated for syphilis and chancroid has reported cure rates of 69% for females and 83% for males.<sup>37</sup> Empirical therapy for both *T. pallidum* and *H. ducreyi* infections should be considered for all patients with GUD in areas like sub-Saharan Africa, where syphilis and chancroid are common. Otherwise, treatment regimens should be directed, usually during the initial visit, towards the most likely diagnosis determined from the clinical presentation and available laboratory studies (see Table 132-3).

In selecting therapy for chancroid, it should be noted that there is widespread resistance of *H. ducreyi* to penicillins (PCNs) and tetracyclines in all geographic areas<sup>38,39</sup>; therefore, these drugs should not be used as part of any treatment regimens. Azithromycin, ciprofloxacin, erythromycin, and ceftriaxone should be used for chancroid treatment, as noted in Table 132-3. Drainage of fluctuant buboes may be necessary. HIV-positive patients may fail single-dose therapy for

\*Needs adaptation to local epidemiological situation.

**FIGURE 132-1** World Health Organization flowchart for the syndromic management of patients with a genital sore or ulcer. (Redrawn from Guidelines for the Management of Sexually Transmitted Infections [WHO/HIV-AIDS/2001.01]. Geneva, World Health Organization, 2001.)

chancroid,<sup>40</sup> and may have increased likelihood of coinfections with syphilis or genital herpes.

Whereas actual resistance of *T. pallidum* to PCN is not known to occur, a significant proportion of patients in the early stages of syphilis fail to demonstrate serologic cure after standard therapy.<sup>41</sup> Serologic cure for syphilis is defined by a four-fold decrease (two or more dilutions) in nontreponemal titers within 6 months after treatment.<sup>42</sup> Serologic treatment failure for primary syphilis has been reported in 5% of HIV-negative patients and 22% of HIV-infected patients at 6 months after standard therapy.<sup>41</sup> Primary syphilis unresponsive to a single dose of PCN should be re-treated with benzathine PCN 2.4 million units intramuscularly (IM), administered weekly for 3 weeks. Alternative regimens for PCN-allergic patients with early syphilis are doxycycline 100 mg orally twice a day or tetracycline 500 mg orally four times a day for 14 days.<sup>7</sup> Oral therapy with azithromycin at 2.0 g orally in a single dose is a potential alternative for treatment of early syphilis.<sup>43</sup> However, there have been a few reported treatment failures with this regimen,<sup>44</sup> especially among HIV-infected persons, underscoring the importance of close follow-up until its treatment efficacy has been fully investigated. Pregnant women with syphilis who are allergic to PCN should be desensitized in a hospital setting, as alternative therapies are inadequate in preventing congenital syphilis. Treatment regimens for HIV-infected persons with early syphilis are the same as for non-HIV-infected persons. However, examination of cerebrospinal fluid should be considered in HIV-positive patients regardless of their stage of syphilis due to their increased risk for early neurosyphilis. Persons with early syphilis should be re-evaluated clinically and serologically using a nontreponemal test after 6 months to assess response to therapy. Repeat evaluations after 6 months and after 12 months may be indicated based on response to therapy and local resources. Re-treatment should be considered for persons with persistent or recurrent clinical signs or symptoms of active syphilis, or persons with a confirmed fourfold (two dilution) increase in the nontreponemal test titers.

There is no known cure for genital herpes, but treatment with acyclovir or its analogues initiated as soon as possible after the onset of symptoms reduces the development of new lesions, the duration of pain, and viral shedding (see Table 132-3). Patients with recurrent herpes should be advised to seek treatment or to start medications during their prodrome phase or within 1 day after onset of lesions in order to benefit from therapy. Patients with recurrent genital herpes (e.g., six or more recurrences per year) are candidates for daily suppressive therapy with acyclovir 400 mg orally twice a day, famciclovir 250 mg orally twice a day, or valaciclovir 500 mg or 1.0 g orally once daily for 6–12 months,<sup>45</sup> followed by reassessment of the need for continued therapy after that period. The safety and efficacy of suppressive therapy with acyclovir has been assessed up to 5 years; more than 20% of patients on suppressive therapy were reported to be recurrence free during this 5-year period.<sup>46</sup> Patients infected concomitantly with HIV can benefit from chronic suppression. However, they may develop thymidine-kinase deficient virus from suppressive therapy, resulting in difficulties with long-term management.

Patients with granuloma inguinale should be given azithromycin or doxycycline, with the addition of gentamicin at 1.0 mg/kg intravenously every 8 hours considered in

difficult cases involving HIV-infected persons. Relapses of granuloma inguinale are frequent and may require a second course of antibiotics. Other drugs which have been reported to be efficacious for this disease include erythromycin, tetracycline, ciprofloxacin, and streptomycin.<sup>33</sup> LGV should be treated with doxycycline or erythromycin for 14 days. However, some patients with advanced disease may require a longer duration of treatment and surgery may be required for sequelae such as strictures and/or fistula.

Medical management of sexual contacts of patients with GUD should include an examination for lesions and empirical treatment in all cases because of the high likelihood of infection. Sexual contacts of patients with genital herpes are an exception, since the infection is not curable and therapy is provided primarily for palliation of symptoms. In addition, education and counseling are critical.

## NONULCERATIVE GENITAL LESIONS

Several STDs may appear as nonulcerative lesions in the genital area (see Table 132-1). Human papillomavirus (HPV) infection resulting in genital warts is frequently encountered in the tropics.<sup>47,48</sup> A cross-sectional study of women attending an STD clinic in Jamaica found that 29% were HPV-positive using Southern blot hybridization techniques on cervicovaginal lavage specimens.<sup>49</sup> HPV in the tropics has been increasingly recognized due to the association of certain “high-risk” HPV types (especially types 16, 18, 31, 33, and 35) with cervical and penile carcinoma. The preceding HPV types are usually associated with subclinical infection in the premalignant phase, while HPV types 6 and 11 cause benign exophytic warts. Concomitant HIV and high-risk HPV may lead to invasive cervical cancer in young women.<sup>50</sup> The pathogenesis of HPV infection involves the squamous epithelium, in which there is viral entry and replication associated with increased proliferation of all the epidermal layers except the basal layer. Effective host defenses are important in the resolution of HPV infections, but these defenses are poorly understood.

Molluscum contagiosum is caused by a large DNA virus of the Poxviridae family resulting in a superficial cutaneous infection of children and young adults. Molluscum is usually a benign condition which may be transmitted through sexual or other close contact, but can occur as an opportunistic infection in patients with AIDS. Scabies should be included in the differential diagnosis of papular lesions in the genital area, as a condition that can also be transmitted through sexual or other close contact. Scabies is caused by *Sarcoptes scabiei* var. *hominis* and is discussed in greater detail in Chapter 118.

## Clinical Manifestations

A patient complaining of vulvar or penile nonulcerative lesions in the absence of other symptoms may have genital warts. Warts are typically multiple, but may be solitary. Genital warts can appear as rough, slightly pigmented papules, flat keratotic plaques, or as soft, fleshy, exophytic lesions called condylomata acuminata. Papular warts usually have the same color as that of the surrounding epithelium; if gray or brown discoloration is present, dysplasia should be suspected. Genital warts may be located on the penile shaft, perineum, labia, or cervix, or in the urethra. Cervical HPV lesions may occasionally present as

classic condylomata acuminata, but are more likely to be sub-clinical. Intra-anal warts are common among men and women who practice receptive anal intercourse.<sup>51</sup> Most patients with genital warts are asymptomatic. Men with genital warts may complain of penile pruritus or bloody ejaculate due to the presence of intraurethral condylomas.

A patient found to have small (2–5 mm), dome-shaped papules with characteristic central umbilication likely has molluscum contagiosum. These lesions are usually pearly white, but can be flesh-colored or yellow. They are typically multiple and may be noted in the inguinal area or inner thighs or in extragenital sites such as the palms, soles, eyelids, and conjunctivae. There may be extensive involvement of the face and torso in AIDS patients.

A patient presenting with highly pruritic polymorphic papules should arouse suspicion of scabies. In early lesions, a tiny dot representing the buried mite may be seen at one end of the papule. The lesions can become excoriated, eczematous, and secondarily infected. When sexually transmitted, the lesions are typically found over the lower abdomen, buttocks, inner thighs, and genitalia. Lesions due to scabies can also appear on the finger webs, ventral wrist fold, and underneath the breasts in women.

## Diagnosis

The diagnosis of genital warts is made primarily on clinical grounds. Physical examination assisted by bright light and magnification is the recommended approach to primary diagnosis.<sup>52</sup> Histopathology of suspicious lesions should be performed in some cases to rule out malignancies. Pelvic examination with cervical and Papanicolaou (Pap) smears is recommended for women suspected of HPV infection. Abnormal cervical lesions should be biopsied for pathologic examination. Condyloma acuminata should be distinguished from the condyloma lata of secondary syphilis, which can form large fleshy masses that frequently erode and have thick secretions loaded with spirochetes. The differential diagnosis of atypical lesions includes genital herpes, molluscum contagiosum, lichen planus, benign neoplasms, genital squamous cell cancer, and Bowen's disease.

Molluscum contagiosum is also diagnosed based on the clinical appearance of the papules. If confirmation is needed, smears of the caseous material expressed from the lesions or a histologic specimen can be examined for characteristic intracytoplasmic inclusions. The differential diagnosis of these lesions is similar to that for genital warts.

The diagnosis of scabies can be made by identifying the typical elongated burrows within the papules, which may be more visible after application of ink. Scrapings of the lesions can be visualized microscopically for the presence of adult mites, larvae, eggs, or fecal pellets. Scabies may be confused with secondary syphilis, atopic or contact dermatitis, drug eruption, and impetigo.

## Management

No therapy has been demonstrated to eradicate HPV once acquired. However, external genital warts can be removed if the patient desires with excisional curettage, electro-surgery, or weekly cryotherapy with liquid nitrogen. Other treatment regimens can be provider or patient administered.

Provider-administered therapies which require careful application to external warts include podophyllin in a 10% to 25% solution or trichloroacetic acid in an 80% to 90% solution applied weekly for up to 6 weeks. Podofilox (a compound purified from podophyllin) in a 0.5% solution may be applied by the patient twice daily for 3 days, followed by 4 days of no treatment, for up to 4 weeks. Imiquimod is a patient-administered immunotherapy for external genital and perianal warts that can be used as a 5% cream applied three times a week for as long as 16 weeks; it may have the advantage of reducing recurrence rates and causing less discomfort to the patient than traditional therapies.<sup>53</sup> Cryotherapy or podophyllin can be used for genital warts located in the vagina or penile urethra. Exophytic cervical warts should be evaluated for dysplasia before initiation of therapy. During pregnancy, the removal of visible warts is advocated because they tend to proliferate and become friable; podophyllin, podofilox, and imiquimod are not recommended as treatment options in pregnancy.

Molluscum contagiosum rarely requires treatment, but for cosmetic reasons or minor symptoms, excisional curettage or cryotherapy is usually effective. Scabies may be treated with 5% permethrin cream or 1% lindane lotion applied to the body for 8 hours and repeated in 1 week. Pregnant women should not be treated with lindane. Bedding and clothing of affected persons should be decontaminated in hot water or a clothes dryer.

Treatment of sexual contacts is not necessary for genital warts or molluscum contagiosum. However, sexual partners to persons with genital warts should be counseled regarding their exposure and risk for disease. Female partners should have a cervical Pap smear. Sexual and other close contacts of patients with scabies should be examined and treated appropriately.

## VAGINAL DISCHARGE

Three general syndromes result in a vaginal discharge: vaginitis or vaginosis, endocervicitis, and ectocervicitis. The type of epithelium present and other factors such as the pH in the microenvironment determine the susceptibility of each site to specific pathogens. The etiologic agents associated with each syndrome are provided in Table 132-1. Trichomoniasis is reported to be the most common nonviral STI worldwide, with reported infection rates as high as 31% among female students and 25% to 38% among pregnant women screened in Nigeria.<sup>54–56</sup> Bacterial vaginosis (BV) is also widely prevalent; in parts of Africa, up to 60% of women presenting with a vaginal discharge have been reported to have BV.<sup>57,58</sup> BV is a clinical syndrome resulting from a disequilibrium of the normal vaginal flora, which consists predominantly of lactobacilli. In BV, there is a massive overgrowth of *Gardnerella vaginalis*, *Mobiluncus* species, and other anaerobes. The role of sexual transmission in BV is controversial<sup>54</sup>; sexual activity may increase the risk for BV through mechanisms such as alteration of vaginal pH. Factors associated with vulvovaginal candidiasis (VVC) include pregnancy, uncontrolled diabetes mellitus, young age, and recent antimicrobial therapy.<sup>58,59</sup> Sexual transmission of candidiasis is infrequent.

While vaginitis and vaginosis are the most common causes of vaginal discharge, cervical infections are more important from a public health standpoint because of their potential complications, including PID, infertility, and neonatal disease.

Trichomoniasis and BV have recently been implicated as causes of obstetric complications (e.g., premature rupture of membranes, low birth weight) and PID.<sup>60–62</sup> However, the association of gonorrhea and chlamydial infection with upper genital tract disease and adverse obstetric and neonatal outcomes is more strongly supported by epidemiologic and biologic data (see the later discussion of PID). Subclinical PID, defined by the presence of histologic endometritis, has been reported among 26% of women infected with *Neisseria gonorrhoeae* and 27% of women infected with *C. trachomatis* in the lower genital tract.<sup>63</sup> Unfortunately, the majority of women infected with *N. gonorrhoeae* and *C. trachomatis* are asymptomatic, making efforts directed at disease detection and prevention challenging.

Gonorrhea has been the most prevalent STI in the tropics. Among low-risk populations attending antenatal or family planning clinics, the prevalence of gonorrhea in tropical countries ranges from 2.0% in India<sup>64</sup> to 3.6% in Tanzania.<sup>65</sup> Among symptomatic women, the prevalence of gonorrhea in Africa has been reported as high as 17.1% in Malawi.<sup>66</sup> Chlamydial infection has a reported prevalence ranging from 1.8% in Brazil<sup>67</sup> to 39.3% in Jamaica<sup>68</sup> among women tested in antenatal or family planning clinics. *N. gonorrhoeae* primarily affects the mucous epithelium of the lower genital tract, resulting in a vigorous neutrophilic response, development of submucosal microabscesses, and exudation of pus. Gonorrhea can also affect the rectum, oropharynx, and conjunctivae, and is discussed in further detail in Chapter 26. The trachoma biovar of *C. trachomatis* primarily affects the squamocolumnar epithelial cells of the endocervix, urethra, rectum, and conjunctiva.<sup>69</sup> Marked inflammation in the upper genital tract of infected women leading to ectopic pregnancy and infertility may be associated with the presence of serum antibodies reactive with the *C. trachomatis* heat-shock protein.<sup>70</sup>

Coinfection with both gonorrhea and chlamydia occurs frequently and should be a consideration in the management of patients with cervicitis. Mucopurulent cervicitis (MPC) is an STI syndrome that is a diagnosis of exclusion. It has been defined as cervical inflammation that is not secondary to *N. gonorrhoeae*<sup>71</sup>; it may be associated with *C. trachomatis* or less frequently with HSV, but in most cases no pathogen is found by routine testing.

## Clinical Manifestations

Symptoms of vaginitis may include discharge, odor, external dysuria, and itching of the vulva and perivaginal mucosa. Patients may also complain of vaginal soreness, irritation, discomfort, and dyspareunia. Unfortunately, the symptoms of vaginitis are nonspecific and differentiation of syndromes cannot be based on these findings alone (Table 132-4). A patient with BV may present with a “fishy” white, homogeneous vaginal discharge in the absence of irritative symptoms. A patient with trichomoniasis may also have a malodorous discharge, but usually have accompanying signs of vulvovaginal irritation such as pruritus and dysuria.<sup>72</sup> A patient presenting with a curdlike vaginal discharge and pruritus of the vulva and perivaginal mucosa is more likely to have VVC.

Both gonococcal and chlamydial cervicitis produce few if any symptoms. When symptoms do occur, they include vaginal discharge, dysuria, and occasionally minor bleeding. Pelvic examination may reveal a purulent, mucopurulent, or bloody cervical discharge, with edema, erythema, or friability of the cervical os. An obvious endocervical discharge or a purulent vaginal discharge originating from the cervix is present in only 10% to 20% of women with gonorrhea.<sup>73</sup> MPC is characterized by the presence of a yellow-green endocervical exudate when viewed on a white cotton swab, or easily induced cervical bleeding when the swab is placed in the endocervix. The presence of mucopurulent discharge along with ulcerations and erythema of the ectocervix should arouse suspicion for HSV.

## Diagnosis

The medical history should include the nature and duration of symptoms, the sexual history (including recent new sex partners), history of prior STDs, past therapy, and response to therapy. The physical examination should include inspection and palpation of the inguinal lymph nodes, vulva, vaginal vestibule, and anorectal area. The color, consistency, volume, and odor of the vaginal secretions should be noted. A speculum examination should be performed when possible to evaluate the vaginal mucosa and cervix for erythema, petechiae, ulceration, edema, atrophy, and adherent discharge.

**Table 132-4 Differential Diagnosis of Vaginitis or Vaginosis**

Feature	Trichomoniasis	Bacterial Vaginosis	Vulvovaginal Candidiasis
Discharge	Thin; gray to yellow-green frothy; mild to fishy odor	Thin; gray to white homogeneous; fishy odor	Thick; white; often curdlike; minimal odor
Vaginal examination	Vulvovaginal erythema	Minimal or no vulvovaginal erythema	Vulvovaginal erythema; mucosal swelling
Cervical examination	Ectocervical erythema; rare punctate hemorrhages (“strawberry cervix”)	Normal	Occasional ectocervical erythema
Wet mount	Trichomonads; increased PMNs	Clue cells; few PMNs	Budding yeast; pseudohyphae; few PMNs
KOH slide	Positive “whiff” test* in some cases	Positive “whiff” test*	Allows clearer view of yeast
pH of discharge	pH > 4.5	pH > 4.5	pH normal (4.0–4.5)

PMN, polymorphonuclear leukocytes.

\*Intensification of foul fishy odor upon addition of KOH to a sample of vaginal discharge.

The differential diagnosis of vaginitis is presented in Table 132-4. Whenever possible, a clinical examination should be accompanied by a wet mount, potassium hydroxide preparation (KOH), and pH determination of the vaginal discharge. The wet mount, performed by mixing vaginal fluid with normal saline on a slide, is examined for polymorphonuclear neutrophils (PMNs), motile trichomonads, and clue cells. Trichomonads are ovoid and slightly larger than PMNs. Clue cells are exfoliated vaginal squamous epithelial cells covered with bacteria, giving the cells a granular or stippled appearance and masking the cell borders. Increased numbers of PMNs (ratio greater than 1:1 relative to epithelial cells) are seen in trichomoniasis, as well as in gonorrhea, chlamydia, and HSV infection. The absence of trichomonads on a wet mount does not exclude the diagnosis since the sensitivity is only 60% to 70% compared with culture, which detects 95% of *T. vaginalis* infections.<sup>74</sup> A wet mount has a sensitivity of 40% to 60% for VVC.<sup>57</sup> The sensitivity can be improved by adding a few drops of 10% KOH to vaginal fluid on a slide to dissolve cellular matter, making yeast forms more visible. The finding of pseudohyphae or budding yeast supports the diagnosis of yeast vaginitis in the setting of appropriate symptoms; however, budding yeast may be part of the normal flora if present in small numbers.

Diagnosis of BV requires three of the following four criteria: (1) a homogeneous, white noninflammatory discharge that adheres to the vaginal walls; (2) the presence of clue cells on microscopic examination; (3) vaginal fluid pH greater than 4.5; and (4) a positive whiff test (a fishy odor before or after addition of 10% KOH to a sample of vaginal discharge).<sup>42</sup> A scoring system based on Gram stain of the vaginal discharge (Nugent criteria) can provide a standardized method for the diagnosis of BV, with a sensitivity of 89%.<sup>75,76</sup> In this scoring system, the absence of lactobacilli, along with the presence of small and curved gram-variable rods (representing *G. vaginalis*, *Bacteroides* species, and *Mobiluncus* species), is most predictive of BV.

Patients suspected of or likely to have cervical infection should be tested for *N. gonorrhoeae* and *C. trachomatis*. The most widely available test for gonorrhea is culture on selective media, which has a reported sensitivity of 86% to 96%.<sup>77</sup> Tissue culture for *C. trachomatis* has a sensitivity of 70% to 80% in experienced laboratories, with a specificity close to 100%,<sup>78,79</sup> but is of limited utility because of its exacting requirements. The sensitivities of both the enzyme immunoassay (EIA) and direct fluorescent antibody (DFA) test for *C. trachomatis* vary, depending on the population being evaluated and skill of the laboratorian. The reported sensitivities range from 73% to 95% for EIA of cervical specimens,<sup>80,81</sup> and 50% to 81% for DFA.<sup>82,83</sup> The specificity of EIA is usually greater than 95%.<sup>84</sup> The specificity of DFA depends on the experience and reliability of the laboratory performing the test. A DNA probe test is also available for the detection of *N. gonorrhoeae* and *C. trachomatis*. The detection of *N. gonorrhoeae* with this test is comparable to culture, and the test has the advantage of requiring only one specimen for identifying both organisms.<sup>85-87</sup> PCR for *N. gonorrhoeae* and *C. trachomatis* using endocervical and urethral specimens provides greater sensitivity and specificity than traditional tests.<sup>88,89</sup> Self-inserted vaginal swabs for PCR detection are also acceptable methods for specimen collection.<sup>90</sup> Urine-based PCR for gonorrhea and chlamydia

has the advantage of being noninvasive and has sensitivities almost equivalent to PCR from endocervical and urethral specimens, but requires first-voided urine specimens for maximum recovery of organisms. However, the cost and the infrastructure required to perform these detection methods may limit their utility in tropical settings.

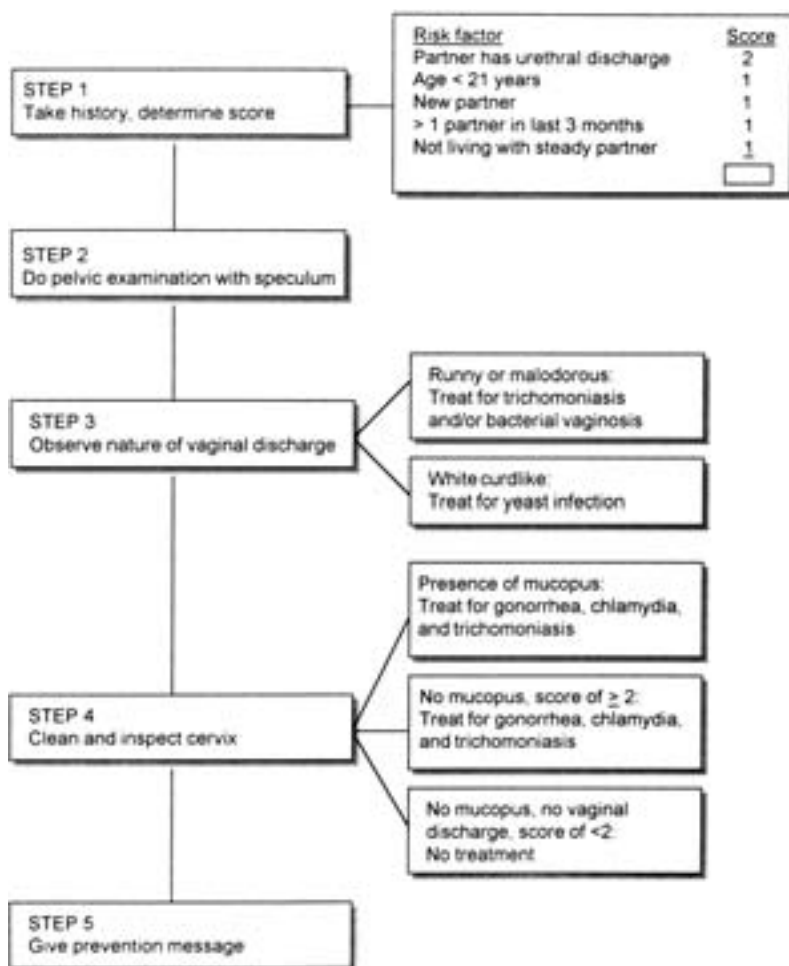

A Gram stain of the cervical discharge may be helpful in choosing empirical therapy, but should be interpreted with caution owing to the limitations of the technique. Increased PMNs, especially greater than 30 per high-power field (HPF), may be correlated with gonococcal or chlamydial infection. When read by an experienced microscopist, the presence of intracellular gram-negative diplococci is 50% to 60% sensitive and highly specific for gonorrhea, while extracellular diplococci may represent normal genital flora. However, the absence of diplococci on an endocervical smear does not exclude gonococcal infection.

In patients with a vaginal discharge but no obvious infectious cause, the differential diagnosis should include chemical or allergic vulvovaginitis, which can result from contact with deodorants, douches, or spermicides, or the presence of a foreign body in the vagina. Cervical, vaginal, and vulvar neoplasias often cause a minor discharge.

## Management

For settings in which a speculum and bimanual examination cannot be performed, the WHO recommends an algorithm for vaginal discharge or vulval itching/burning based on the presence of an abnormal discharge, lower abdominal tenderness, and a risk assessment adapted to the local social, behavioral, and epidemiological situation. When the patient has an abnormal discharge and a positive risk assessment, this algorithm recommends empiric treatment for gonococcal, chlamydial and trichomonal infections, and BV.<sup>8</sup> An algorithm for the syndromic management of patients presenting with a vaginal discharge is provided as an example in Figure 132-2. This algorithm requires a risk assessment and a speculum examination and was found to be 84% sensitive and 40% specific for the presence of a cervical infection in a Jamaican STD clinic.<sup>12</sup> Recommended therapies for vaginitis and cervicitis are provided in Table 132-5. The single oral dose of 2 g metronidazole for trichomoniasis has a cure rate of 82% to 88%.<sup>91</sup> Due to the occurrence of *T. vaginalis* with resistance to metronidazole, infections that do not respond to the single-dose regimen should be re-treated with metronidazole 500 mg twice a day for 7 days. If treatment failure recurs, the patient should be treated with metronidazole 2 g orally once daily for 3 to 5 days. The single-dose regimen of 2 g metronidazole for BV has clinical response rates comparable to the standard regimen, but higher recurrence rates have been reported.<sup>92,93</sup> Pregnant women who have symptomatic BV can be treated with metronidazole at 250 mg orally three times a day for 7 days, or with a single 2-g dose. Alternative therapies in pregnancy include topical metronidazole gel and oral clindamycin. There are several topical antimycotic agents for VVC with similar clinical efficacies. Oral therapy for VVC with fluconazole 150 mg as a one-time dose is superior to these topical therapies; however, fluconazole is expensive and should be avoided in pregnancy. Recurrent VVC, usually defined as three or more episodes per year, occurs in a minority of patients with risk factors such as immunosuppression or corticosteroid use.

**FIGURE 132-2** Example of a flowchart for the management of patients with a vaginal discharge. (From Behets PMT, Williams Y, Brathwaite A, et al: Management of vaginal discharge in women treated at a Jamaican sexually transmitted disease clinic: Use of diagnostic algorithm versus laboratory testing. Clin Infect Dis 21:1450, 1995.)

**Table 132-5** Recommended Treatment Regimens for Vaginitis, Cervicitis, and Urethritis

Trichomonas vaginitis/urethritis	Metronidazole 2 g PO $\times$ 1 dose; or tinidazole 2 g PO $\times$ 1 dose (Alternatives: metronidazole 500 mg PO bid $\times$ 7 days; or tinidazole 500 mg PO bid $\times$ 5 days) (Pregnancy: metronidazole 2 g dose as above)	
Bacterial vaginosis	Metronidazole 500 mg PO bid $\times$ 7 days (Alternatives: metronidazole 2 g PO $\times$ 1 dose; or metronidazole gel 0.75% 5 g intravaginally bid $\times$ 5 days; or clindamycin 300 mg PO bid $\times$ 7 days; clindamycin cream 2% 5 g intravaginally at bedtime $\times$ 7 days) (Pregnancy: metronidazole 250 mg PO tid $\times$ 7 days or the 2 g dose, metronidazole gel or clindamycin as above)	
Candida vaginitis	Miconazole or clotrimazole 200 mg intravaginally every day $\times$ 3 days; or clotrimazole 500 mg PO intravaginally $\times$ 1 dose; or fluconazole 150 mg PO $\times$ 1 dose; (Alternative: nystatin 100,000 IU intravaginally every day $\times$ 14 days) (Pregnancy: any 7-day topical treatment)	
Gonococcal cervicitis/urethritis*	Ciprofloxacin 500 mg PO $\times$ 1 dose <sup>†‡§#</sup> ; or ofloxacin 400 mg PO $\times$ 1 dose <sup>†‡</sup> ; levofloxacin 250 mg PO $\times$ 1 dose <sup>†‡</sup> ; cefixime 400 mg PO $\times$ 1 dose <sup>‡</sup> ; or ceftriaxone 125 mg IM $\times$ 1 dose <sup>‡§#</sup> ; or spectinomycin 2 g IM $\times$ 1 dose <sup>‡#</sup> (Pregnancy: cefixime, ceftriaxone, or spectinomycin as above)	} plus treatment for <i>C. trachomatis</i>
Chlamydial cervicitis/urethritis*	Doxycycline 100 mg PO bid $\times$ 7 days; or azithromycin 1 g PO $\times$ 1 dose; (Alternatives: amoxicillin 500 mg PO tid $\times$ 7 days; erythromycin base 500 mg PO qid $\times$ 7 days; ofloxacin 300 mg PO bid $\times$ 7 days; tetracycline 500 mg PO qid $\times$ 7 days) (Pregnancy: amoxicillin or erythromycin as above)	
Nongonococcal urethritis	Doxycycline 100 mg PO bid $\times$ 7 days; or azithromycin 1 g PO $\times$ 1 dose; or erythromycin base 500 mg PO qid $\times$ 7 days	

\*Regimen is for uncomplicated cervicitis or urethritis only.

<sup>†</sup>Knowledge of local resistance patterns is recommended due to increasing fluoroquinolone resistance.

<sup>‡</sup>Regimens recommended for anorectal infections.

<sup>§</sup>Regimens recommended for treatment of gonococcal pharyngitis.

<sup>#</sup>Regimens recommended for treatment of adult gonococcal conjunctivitis.

The frequency of episodes can be reduced with a regimen of ketoconazole 100 mg orally once daily or fluconazole 100 mg orally once weekly for 6 months.<sup>94</sup> Chronic suppressive therapy may be required for patients with HIV/AIDS who may have severe episodes of VVC and frequent relapses.

Treatment regimens for gonorrhea and chlamydial infection require several considerations, including antimicrobial resistance of *N. gonorrhoeae*, concurrent infection, and involvement of the upper genital tract. Resistance of *N. gonorrhoeae* to PCN and tetracycline has been well recognized in developing countries, with more than 50% of strains in Africa reported to be penicillinase-producing.<sup>95,96</sup> Resistance to *N. gonorrhoeae* has also been reported for spectinomycin.<sup>97</sup> Fluoroquinolone resistance is common in much of southeast Asia and is increasingly recognized in other parts of the world.<sup>98,99</sup> Alternative regimens with kanamycin or trimethoprim-sulfamethoxazole is recommended only for countries with low in vitro resistance in which patients treated with these regimens can be closely monitored.<sup>7</sup> Because of the high likelihood of coinfection, persons treated for gonorrhea should also receive treatment that is effective against *C. trachomatis*. Doxycycline and azithromycin have similar efficacy against *C. trachomatis*; the choice of regimen depends on cost and expected patient compliance. Azithromycin is administered as a single-dose regimen and may be more cost-effective since successful therapy with doxycycline requires compliance with a 7-day course. Empirical treatment of both gonorrhea and chlamydial infection should be considered for patients with mucopurulent cervicitis, especially in populations with a high prevalence of these infections and when laboratory testing is not available.

Treatment and counseling should be provided for sex partners of patients with trichomoniasis, gonococcal, or chlamydial infection. There is an increased cure rate of trichomoniasis in women following treatment of their male sexual partners.<sup>100</sup> In the absence of definitive laboratory diagnosis, patients should be told that an infection with an STI is possible but not proven, requiring treatment of the patient and all sex partners. Treatment of sex partners is not required for BV or VVC.

## URETHRAL SYNDROMES AND URINARY TRACT INFECTIONS IN WOMEN

Urethral syndromes in women may present as urethritis caused by STIs or cystitis caused by urinary tract pathogens. The causative organisms associated with urethritis in women include *N. gonorrhoeae*, *C. trachomatis*, and HSV infection. The microbiology of UTIs is the same worldwide. Most uncomplicated infections, usually over 80%, are due to *Escherichia coli*. Between 5% and 10% of infections, particularly in females, are due to *Staphylococcus saprophyticus* and the remainder are due to a variety of aerobic organisms. Complicated UTIs are also most commonly due to *E. coli*, but the strains are often more resistant to antimicrobial agents and occur following selection within an institutional environment or secondary to the effects of repeated courses of antibacterial therapy. *Klebsiella* spp., *Proteus* spp., *Pseudomonas aeruginosa*, *Enterococcus* spp., and *Candida* spp. occur much more frequently in patients with underlying structural or functional abnormalities and in patients who have acquired infection nosocomially. Anaerobes and more fastidious organisms are rarely responsible for UTIs and are found in fewer than 3% of patients.

In tropical countries, *Salmonella* spp., particularly *S. typhimurium*, are common causes of UTI. In Egypt, *Salmonella* may account for 10% to 20% of the complicated urinary infections.<sup>101</sup> *Salmonella* spp. are also very common in patients who have concomitant infection with *Schistosoma haematobium*.<sup>101</sup> These patients may have bladder calculi so that management can be complex and require careful treatment of infection, as well as dissolution of calculi.

*Mycobacterium tuberculosis* urinary infection is common in tropical countries and must be considered in all patients who present with symptoms of UTI with pyuria and otherwise "sterile" urine cultures. Genitourinary tuberculosis is discussed elsewhere. *Brucella* spp. can cause chronic urinary infection with granulomatous pyelonephritis or cystitis.

## Clinical Manifestations

Women with urethritis secondary to STIs may present with dysuria, urinary frequency, and lower abdominal pain, and concomitant symptoms associated with cervicitis or vaginitis. Urethritis should be differentiated from acute cystitis, which may also present with dysuria, frequency, and lower abdominal pain, and be accompanied by urinary urgency and/or gross hematuria. Additional symptoms of fever, chills, flank pain, and systemic complaints should raise suspicion for pyelonephritis. In about one-fourth of women with pyelonephritis, subsequent bacteremia can lead to the "sepsis syndrome." Asymptomatic bacteriuria occurs commonly with a prevalence of 3% to 10% in otherwise healthy adult women. Pregnant women with asymptomatic bacteriuria are predisposed to developing invasive pyelonephritis and other complications; therefore, these women should be routinely screened for urinary tract disease.

## Diagnosis

Women with urethral symptoms should have a urinalysis, a urine culture, a sexual risk assessment, and a pelvic examination whenever possible to differentiate urinary infection from the various STI syndromes.

The laboratory diagnosis of gonococcal, chlamydial, and HSV infections are discussed in previous sections. Laboratory diagnosis of UTI requires demonstration of pyuria and bacteriuria. A clean-catch midstream urine specimen with 10 or more leukocytes per high-power field (HPF) supports the diagnosis of infection if no other cause of pyuria is present. Leukocyte esterase and nitrite strips can be used to screen urine for evidence of infection, but the sensitivity is usually less than 90% and specificity about 80%.<sup>102</sup> A presumptive diagnosis of UTI may be achieved with a microscopic examination revealing 5 to 10 organisms per oil immersion field on Gram stain. Quantitative urine cultures should be requested on clean-voided midstream urine and quickly transported to the laboratory. However, if an immediate culture is not feasible, storage for 24 hours at 4°C in a refrigerator maintains bacterial stability. Urine cultures are of no value if specimens have been improperly collected and stored, as bacteria grow readily in urine and urine cultures will be falsely positive. Urine is cultured on blood agar and selective media (such as MacConkey's agar) with a quantitative loop that enables an estimation of the bacterial count (colony-forming units, CFU).

Determination of the antimicrobial susceptibilities of the bacterial isolates may be important in patients with complicated infections. Pyuria is almost invariably present in patients with symptomatic urinary infections. Of note, between 10% and 50% of patients with acute symptoms will have bacterial counts of less than  $10^8$  CFU/L or less than  $10^5$  CFU/mL.<sup>103</sup> “Low count” bacteriuria is a real entity; in both males and females with symptoms, it usually portends infection. On the other hand, asymptomatic bacteriuria in females should usually be diagnosed only if at least two urine cultures have counts of greater than  $10^8$  CFU/L ( $10^5$  CFU/mL).

For women who are prone to UTIs and have had multiple recurrences, symptomatic episodes should be managed with as little investigation as possible. A urinalysis may be all that is required for diagnosis.

## Management

Management of women with suspected STIs has been discussed previously. Treatment of acute cystitis has been standardized to a 3-day oral regimen with trimethoprim 160 mg and sulfamethoxazole 800 mg twice daily or cephalexin 500 mg four times daily. If resistance among *E. coli* strains to these agents is widespread in the community, the fluoroquinolones are effective treatment choices. Most *E. coli* strains that cause acute uncomplicated cystitis are now resistant to amoxicillin.

Women who present with presumed acute pyelonephritis require urgent attention. Alternative diagnoses, particularly surgical conditions, acute PID, ectopic pregnancy, and other illnesses, need to be excluded. About one-third of patients initially diagnosed as having acute pyelonephritis are found to have other illnesses. Women should have urine and blood cultures and be treated immediately with an effective regimen. Ampicillin and gentamicin are appropriate for initial parenteral therapy; oral regimens may then be prescribed for 2 weeks. The fluoroquinolones are satisfactory oral choices for patients with acute pyelonephritis if the infecting pathogen is susceptible.

Recurrence of infection should be anticipated in women with UTIs. Recurrent symptomatic cystitis is best managed by continuous low-dose prophylaxis or with intermittent prophylaxis taken with intercourse.<sup>104</sup> Trimethoprim-sulfamethoxazole or a fluoroquinolone is the most effective prophylactic agent. Women with recurrent UTIs may be given medication to initiate self-treatment when their symptoms recur. Postmenopausal women may respond to local vaginal estrogens with dramatic reductions in the number of recurring episodes of cystitis.<sup>105</sup> Recurring renal infection mandates studies to exclude abnormalities in the upper tract. Some women will require continuous suppression to prevent recurring symptoms.

All pregnant women should be screened for infection with a urinalysis and a urine culture. Asymptomatic bacteriuria should be treated; this will prevent over 80% of acute episodes of pyelonephritis in pregnancy and will also prevent 10% to 20% of premature deliveries. All pregnant women who have a urinary infection should be followed with frequent urinalysis throughout their pregnancy. Asymptomatic infections are usually treated in children but not in adults or in individuals with indwelling catheters unless there is evidence of invasive disease.

## URETHRAL SYNDROMES AND URINARY TRACT INFECTIONS IN MEN

Urethral syndromes in men are classified as urethritis, epididymitis, prostatitis, cystitis, and pyelonephritis. In sexually active men, *N. gonorrhoeae* and *C. trachomatis* are the most common causes of urethritis and epididymitis. The prevalence of gonorrhea among males presenting with a urethral discharge varies from 50% to 60% in Africa.<sup>106,107</sup> In comparison, the prevalence of chlamydial infection among males presenting with a urethral discharge varies from 12.3% in parts of Africa to 53.4% in Jamaica.<sup>66,108</sup> Approximately one-half to three-fourths of cases of nongonococcal urethritis (NGU) are caused by other pathogens, including *Ureaplasma urealyticum*, *Mycoplasma genitalium*, *T. vaginalis*, or HSV. *M. genitalium* has gained increased recognition as a causative agent of acute and chronic NGU and appears to act independently of *C. trachomatis* with approximately the same frequency.<sup>109</sup> *T. vaginalis* may be a particularly important cause of urethritis in some tropical areas such as Africa, where 19% of males presenting with urethral discharge were diagnosed with *T. vaginalis*.<sup>110,111</sup>

*E. coli* and other urinary tract pathogens can also present as urethritis, epididymitis, and prostatitis; an initial empirical treatment regimen should include all of these organisms in its spectrum. UTIs occur with an incidence of about 1 per 100 during the first year of life in boys. These infections are often associated with underlying congenital anomalies. The presence of a foreskin increases the incidence of UTIs in boys and in adult men by two- to threefold.<sup>112</sup> During adult life, the annual incidence is approximately 3 per 1000, which increases dramatically during the seventh decade with the onset of prostatic disease.

## Clinical Manifestations

A patient with urethritis may present with a urethral discharge, dysuria, or itching at the meatus. Gonorrhea typically develops 2 to 6 days after exposure, whereas NGU may take 1 to 5 weeks from exposure to the onset of symptoms. Gonococcal and NGU can be differentiated by the clinical manifestations in up to three-fourths of cases. A profuse, yellow-green discharge with an acute onset is suggestive of gonococcal origin, while a mucopurulent or mucoid discharge noted only after urethral stripping or in the morning before voiding is likely to be nongonococcal in etiology. However, atypical presentations may occur as a result of self-medication, a common practice in the tropics.<sup>113</sup> Crusting at the urethral meatus may be the only manifestation of NGU in some men. Dysuria is present in both conditions, but the presence of dysuria without a urethral discharge is a very good predictor of NGU. A profuse mucoid discharge with severe dysuria suggests HSV, especially if accompanied by regional lymphadenopathy and external genital lesions.

Urinary frequency, urgency, and hematuria are not generally part of the urethritis syndrome in men, and suggest the presence of prostatitis, cystitis, or other disorders. Asymptomatic bacteriuria is less common in men, usually occurring with the onset of prostatic hypertrophy or cancer and urinary tract obstruction. Prostatitis usually presents with perineal and lower abdominal pain, fever, burning, frequency, and occasionally with a sepsis-like syndrome.

## Diagnosis

A Gram stain should be performed on the urethral discharge and examined for the presence of greater than 4 PMNs per HPF as objective evidence of urethritis. When the discharge is minimal or absent, a thin endourethral swab should be inserted 2 to 4 cm into the urethra and rolled onto a glass slide. The finding of gram-negative intracellular diplococci is highly specific for gonococcal urethritis (95% sensitivity, 98% specificity), but a negative smear does not exclude gonorrhea, particularly in cases where self-medication is suspected. If PMNs are present but no intracellular organisms are seen, a tentative diagnosis of NGU should be made. Additional tests should be obtained for *N. gonorrhoeae* and *C. trachomatis* when possible. In areas with limited laboratory resources, the leukocyte esterase test can be performed on the first-voided portion of urine from symptomatic men with urethritis; this dipstick measurement has a reported sensitivity of 76% and specificity of 80% for the presence of gonorrhea or chlamydia in one study involving STD clinic patients.<sup>114</sup> Trichomonads may occasionally be found on Gram stain or on a wet mount of urethral discharge. Testing for *U. urealyticum* is seldom clinically useful since the organism frequently colonizes the urethra. In the patient with symptoms suggestive of urethritis but with less than 4 PMNs per HPF on the Gram stain, a second examination may be helpful. After several hours without micturition, urethral stripping may produce a small amount of discharge which can be examined microscopically.

Males with UTI are often investigated to exclude congenital or acquired abnormalities.<sup>115</sup> An intravenous pyelogram or an ultrasound examination should be combined with a cystoscopic study. Since the majority of adult men will not have an underlying anatomic abnormality as a predisposing factor for their UTIs, the recurrence of infection is an excellent indicator for men who require further investigation. Men with chronic

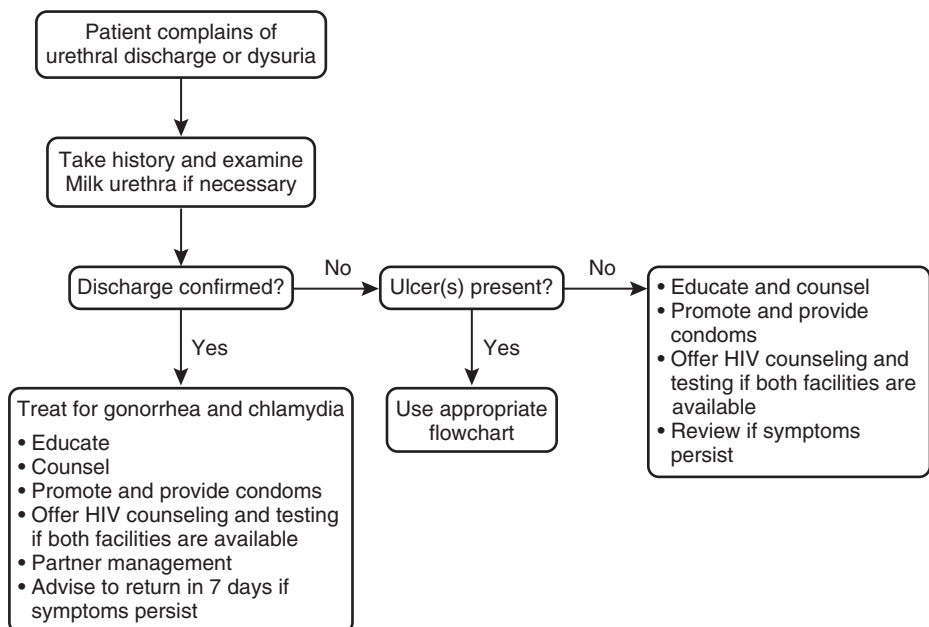

prostatitis should have a culture performed on expressed prostatic secretions to identify the bacterial etiology.

## Management

The WHO flowchart (Fig. 132-3) is provided as an example of the syndromic management of patients presenting with a urethral discharge; it is a simple flowchart recommending treatment of gonorrhea and NGU for every man with evidence of a urethral discharge. Use of a similar algorithm whereby all men with a urethral discharge were treated with either ceftriaxone or ciprofloxacin combined with doxycycline resulted in 92% clinical success in primary health clinics in Côte d'Ivoire.<sup>22</sup> In areas with a high prevalence of gonococcal and chlamydial infection, or where tests are not available, empirical treatment aimed at both *N. gonorrhoeae* and *C. trachomatis* for all patients with urethritis can be a cost-effective option. The recommended therapies for urethritis are given in Table 132-5. Because of the high cost of some medications, alternative therapies such as gentamicin and kanamycin for gonorrhea may be reasonable options in some settings depending on local antimicrobial susceptibilities.<sup>116</sup> Men with persistent or recurrent urethritis despite appropriate therapy may be given erythromycin 500 mg orally four times a day for 14 days as treatment for presumptive tetracycline-resistant *U. urealyticum* or metronidazole 2 g orally once for trichomoniasis. Recurrence of NGU days to weeks after therapy may be due to a prostatic focus of infection and may be treated with a 3- to 6-week course of doxycycline, erythromycin, or azithromycin. Sex partners of patients with trichomoniasis, gonorrhea, chlamydial infection, or NGU require presumptive treatment and counseling.

Males of all ages with lower tract infection should be treated with a 14-day course of an effective antibacterial regimen.

**FIGURE 132-3** World Health Organization flowchart for the syndromic management of patients with a urethral discharge or dysuria. (Redrawn from Guidelines for the Management of Sexually Transmitted Infections [WHO/HIV-AIDS/2001.01]. Geneva, World Health Organization, 2001.)

Trimethoprim–sulfamethoxazole is an acceptable initial regimen. Patients with symptoms of prostatitis and patients who have recurrence after an initial 14-day course of treatment should be given trimethoprim–sulfamethoxazole for at least 6 weeks. Long courses are necessary to eradicate infection in some men. Men with acute pyelonephritis should be treated initially with parenteral regimens; continuing treatment for 14 days should be prescribed with an oral regimen such as trimethoprim–sulfamethoxazole or a fluoroquinolone. These drugs achieve satisfactory levels within prostatic tissue and are more likely to eradicate the organism from this site.

Chronic prostatitis is a problematic diagnosis since proof of bacterial infection is necessary. For men with relapsing chronic prostatitis, continuous therapy may be necessary to prevent recurrences.

### LOWER ABDOMINAL PAIN

Sexually active women presenting with lower abdominal pain should be evaluated for PID or an ascending infection of the uterus, fallopian tubes, and adjacent pelvic structures resulting in endometritis, salpingitis, pelvic peritonitis, or tuboovarian abscess. The long-term sequelae of undetected disease include infertility, ectopic pregnancy, and chronic pelvic pain. In sub-Saharan Africa, the majority of cases (85%) of infertility are due to bilateral tubal occlusion resulting from PID.<sup>117</sup> PID is frequently encountered in tropical countries, where the annual incidence in urban women aged 15 to 35 years has been estimated to be 1% to 3%.<sup>118</sup> Most cases of PID are caused by *N. gonorrhoeae*, *C. trachomatis*, and anaerobic flora of the gastrointestinal and genital tracts (e.g., *Bacteroides* spp.). Approximately 30% to 40% of cases are associated with mixed infections of both aerobic and anaerobic organisms.<sup>119–121</sup> Organisms associated with bacterial vaginosis contribute to some cases of PID,<sup>122</sup> while in 20% of cases no cause has been found.<sup>119</sup> *Mycoplasma genitalium* has been recently associated with PID.<sup>123,124</sup> Predisposing factors for PID include young age, multiple sex partners, use of intrauterine devices, douching, and prior history of PID.<sup>125,126</sup>

### Clinical Manifestations

A patient presenting with lower abdominal pain accompanied by an abnormal vaginal discharge should be suspected

of having PID. Other symptoms suggestive of PID include abnormal uterine bleeding, dysuria, dyspareunia, menometrorrhagia, pain associated with menses, nausea, vomiting, and fever. Gonococcal PID is more likely when there is an abrupt onset of symptoms such as fever and abdominal pain. Physical examination may reveal a purulent cervical discharge, cervical motion, and adnexal tenderness. A patient presenting with symptoms of PID and pleuritic upper abdominal pain should raise suspicion for perihepatitis and peritonitis due to extension of the infection to the subphrenic and subdiaphragmatic space, a condition known as the Fitz-Hugh–Curtis syndrome.

### Diagnosis

The diagnosis of PID is usually based on the minimum clinical criteria of lower abdominal pain together with cervical motion and adnexal tenderness. Laparoscopic visualization has been considered the gold standard but is usually not warranted. The minimum criteria for PID has a reported sensitivity of 83% compared to endometrial sampling, in comparison with a 95% sensitivity for adnexal tenderness.<sup>127</sup> Additional criteria which may increase the specificity of diagnosis include fever, abnormal discharge, and laboratory documentation of cervical infection. A pelvic examination should be performed to determine the presence of any cervical discharge, uterine, adnexal, or cervical motion tenderness, or masses. Endocervical specimens should be obtained and tested for *N. gonorrhoeae* and *C. trachomatis*. Laboratory examination for other organisms associated with PID is not useful since they are often part of the normal flora in healthy women. The differential diagnosis of acute lower abdominal pain in women includes pregnancy, appendicitis, ovarian cyst, diverticular disease, urinary tract infections, and enteric illnesses.

### Management

Empirical therapy for PID should be instituted in the presence of the minimum clinical criteria and in the absence of another established cause of the patient's symptoms. Because of the difficulty in determining the exact infectious cause of PID, treatment should be directed at all potential pathogens and should be broad-spectrum in nature. Effective inpatient and outpatient regimens for PID are presented in Table 132-6. Antibiotic therapy should be continued for

**Table 132-6 Recommended Treatment Regimens for Pelvic Inflammatory Disease**

Inpatient regimens	Cefoxitin 2 g IV every 6 hours (hrs); or cefotetan 2 g IV every 12 hrs; or ceftriaxone 250 mg IM × 1 q day* Plus doxycycline 100 mg IV or PO every 12 hrs × 14 days Plus metronidazole 500 mg IV or PO bid × 14 days
Outpatient regimens	Clindamycin 900 mg IV every 8 hrs plus gentamicin 1.5 mg/kg IV every 8 hrs*† Ceftriaxone 250 mg IM × 1 dose, or cefoxitin 2 gm IM with probenecid 1 gm PO × 1 dose Plus doxycycline 100 mg PO bid or tetracycline 500 mg PO qid × 14 days Plus metronidazole 500 mg PO bid × 14 days Ofloxacin 400 mg PO bid × 14 days; or levofloxacin 500 mg PO once daily × 14 days Plus metronidazole 500 mg PO bid × 14 days

\*These regimens should be continued for at least 48 hours after clinical improvement and then followed by an oral regimen to complete 14 days of therapy.  
†After discontinuation, this regimen should be followed by either doxycycline 100 mg PO bid or tetracycline 500 mg PO qid to complete 14 total days of therapy.

a 10- to 14-day course; the clinical efficacy of these regimens ranges from 81% to 94%.<sup>128,129</sup> Azithromycin as a single dose is effective for chlamydial endocervicitis but has not been studied in the treatment of PID. Hospitalization is required in a substantial but ill-defined proportion of women with PID in developing countries.<sup>118</sup> Hospitalization is generally recommended when the diagnosis is uncertain, the possibility of a surgical emergency cannot be excluded, a pelvic abscess is suspected, the patient is pregnant or immunocompromised, severe illness precludes outpatient management, the patient cannot tolerate an outpatient regimen, or the patient has failed to respond to outpatient therapy. Reassessment of the patient after 72 hours is recommended to evaluate the response to outpatient treatment. Removal of an intrauterine device, which is a risk factor for the development of PID, is recommended after initiation of antimicrobial therapy. Because of the risk of reinfection, sex partners of women with PID should be evaluated and empirically treated with regimens that are effective against both *N. gonorrhoeae* and *C. trachomatis*. Bed rest, avoidance of sexual intercourse during therapy, and evaluation of the male sexual partner are integral components of PID management. The woman and her partner(s) should be counseled appropriately; when a definite laboratory diagnosis is not possible, patients should be told that an STI is suspected, requiring treatment of the woman and all partners.

## SCROTAL SWELLING

Men presenting with scrotal swelling should be evaluated for epididymitis, an acute inflammation of the epididymis which is usually a complication of gonococcal or chlamydial urethritis in men less than 35 years of age. Unlike PID, ascending infection from *N. gonorrhoeae* or *C. trachomatis* to the epididymis is uncommon except in areas where treatment facilities are inadequate or nonexistent. Extension of the infection to involve the adjacent testicle results in epididymo-orchitis. In older men, epididymitis is more commonly associated with enteric organisms (e.g., *E. coli*, *Klebsiella* spp.). Other organisms that should be considered as a cause of epididymitis include *Mycobacterium tuberculosis*, *Brucella* spp., and blastomycosis, which is usually accompanied by orchitis or disease elsewhere such as in the lungs or bones.

## Clinical Manifestations

The presence of acute scrotal swelling with scrotal and inguinal pain suggests the possibility of epididymitis. Testicular torsion can manifest with similar symptoms and must be differentiated because it is a surgical emergency. Symptoms of epididymitis usually begin unilaterally, but may soon progress to a bilateral epididymo-orchitis. Physical examination may reveal a swollen, tender epididymis and vas deferens, and a red, edematous scrotum. Symptoms of urethritis may also be present. Approximately half of patients presenting with epididymitis of gonococcal origin have a urethral discharge.

## Diagnosis

Simple laboratory tests can help with the diagnosis of epididymitis. A urethral smear revealing greater than 4 PMNs per HPF provides objective evidence of urethritis, and supports the

diagnosis of epididymitis in a man with scrotal pain. A urethral swab or urine specimen should be obtained and tested for *N. gonorrhoeae* and *C. trachomatis*. Urinalysis and urine culture can determine the presence of an associated urinary tract infection. The differential diagnosis of scrotal swelling includes testicular torsion, orchitis secondary to non-sexually transmitted pathogens, hydrocele, spermatocele, and testicular carcinoma.

## Management

Empirical therapy of epididymitis is recommended while awaiting test results. Patients suspected of having an STI should be treated for both *N. gonorrhoeae* and *C. trachomatis*, using ceftriaxone 125 mg IM in a single dose plus doxycycline for 10 days. Ofloxacin 300 mg orally twice a day for 10 days is an alternative regimen that is effective against both organisms, as well as against gram-negative bacilli which may be associated with a UTI. Bed rest with scrotal elevation and application of ice packs may assist in decreasing local inflammation and swelling. Sex partners of men with epididymitis thought to be of gonococcal or chlamydial etiology should be evaluated and treated.

## OTHER CLINICAL PRESENTATIONS OF SEXUALLY TRANSMITTED INFECTIONS

STIs can present less commonly as other clinical syndromes including proctitis, pharyngitis, conjunctivitis, and hepatitis, depending on the site of exposure or the propensity of the organism to affect certain organ systems (see Table 132-1). Patients with proctitis may present with a rectal discharge, anorectal pain, or tenesmus. In sexually active individuals, especially men who have sex with men who engage in receptive anal intercourse, empiric treatment with ceftriaxone 125 mg IM and doxycycline for 7 days should be considered when an anorectal exudate or PMNs on a Gram stain of the anorectal secretions is found on examination. Patients with a history of oral sexual activity, especially fellatio, may present with a sore throat, acute pharyngitis, or tonsillitis secondary to gonorrhea. Chlamydial infection of the pharynx is unusual; however, empiric therapy should be directed towards both pathogens when gonococcal pharyngitis is suspected since co-infections can occur. Conjunctivitis in adults secondary to STIs may result from oculogenital contact, as well as direct or indirect contact from digits or fomites from infected persons. Patients with conjunctivitis secondary to gonorrhea may present with an acute mucopurulent discharge of the conjunctiva, redness, or swelling. The presentation and management of viral hepatitis are presented in greater detail in Chapter 64. Sexual activity is a significant risk factor for acquisition of hepatitis A, hepatitis B, hepatitis C, and cytomegalovirus infections.

## SEXUALLY TRANSMITTED INFECTIONS–HUMAN IMMUNODEFICIENCY VIRUS INTERACTIONS

The epidemiologic and biologic associations between STIs and HIV infection underscore the importance of integrating STI/HIV management in clinical settings. Many STIs appear to serve as cofactors facilitating HIV transmission, while HIV infection itself appears to alter the natural history and therapeutic response of some STIs. Biological studies have shown

that persons with STIs have increased susceptibility to HIV by the presence of increased inflammatory cells and disruptions in their genital mucosa, and that the presence of other STIs in HIV-infected persons facilitates shedding of the virus in their genital tracts, thereby promoting HIV infectiousness.<sup>130-132</sup>

Among the STIs, GUD has been found to have the strongest association with HIV.<sup>133</sup> Studies have also shown associations between HIV infection and gonorrhea,<sup>134,135</sup> chlamydial infection,<sup>136</sup> trichomoniasis,<sup>134</sup> bacterial vaginosis,<sup>137</sup> and genital warts,<sup>138</sup> independent of other risk factors for HIV infection, including sexual behavior. The higher prevalence of nonulcerative STIs makes them equally important as GUD as cofactors for HIV transmission. Therefore, prompt and appropriate treatment of STIs is important in limiting the spread of HIV infection. HIV voluntary testing and counseling should be offered to patients presenting with STIs. HIV-positive persons may have rapid progression or severe manifestations of STIs such as syphilis, HSV, or HPV. Patients with HIV infection may be less responsive to standard antibiotic therapy for chancroid,<sup>139</sup> syphilis,<sup>41,140</sup> genital HSV,<sup>141</sup> and HPV.<sup>142</sup>

## CONTROL OF SEXUALLY TRANSMITTED INFECTIONS

Effective STI control cannot be achieved solely on the basis of correct diagnosis and prompt treatment of symptomatic patients. Primary prevention programs including culturally appropriate sex education through schools and religious institutions, encouragement of delay in sexual debut among adolescents, programs to encourage gender respect and equity including educational opportunities for girls, supportive sex-worker interventions, marriage support initiatives, prenatal screening programs, and condom access programs are all important to provide a foundation on which to build secondary control programs. Behavioral change plays a crucial part in the control of STIs and should be addressed through individual counseling or comprehensive health education programs emphasizing safe sex practices and condom use. In developing countries, public health interventions targeting groups with the highest rates of sex partner change (e.g., commercial sex workers) may improve the cost-effectiveness of HIV and other STI prevention efforts. In addition to strategies on the individual level, community-oriented approaches to STI control may be helpful in settings where STIs are highly prevalent.<sup>143-145</sup>

Partner notification and screening among at-risk individuals are integral components of secondary STI control programs due to the fact that a significant proportion of persons infected with STIs, especially women, have no symptoms. Partners of patients with STIs should be contacted for evaluation and treatment to decrease the reservoir of potentially infectious persons. STI screening should be considered in areas of high prevalence or among high-risk groups, depending on available laboratory techniques and resources. Screening of pregnant women for STIs, especially syphilis, is important and should be performed at the first prenatal visit and again in the third trimester for individuals at high risk for exposure. The promotion of condom use and other barrier methods is imperative and can decrease the rate of transmission of STIs and HIV. Though nonoxynol-9 was not found to reduce male-to-female transmission of STIs,<sup>146,147</sup> efforts are continuing to develop safe and

acceptable topical microbicides that could inactivate STIs including HIV.

# Approach to the Patient with HIV and Coinfecting Tropical Infectious Diseases

CHRISTOPHER L. KARP  
ROBERT COLEBUNDERS

All ... fall into one of two categories: Infected with HIV or at risk for HIV infection.

Mary E. Wilson<sup>1</sup>

## INTRODUCTION

The morbidity, mortality, and social disruption due to the global acquired immunodeficiency syndrome (AIDS) pandemic weigh disproportionately upon resource-poor areas of the tropics.<sup>2</sup> Because these are the very areas where “tropical” infectious diseases continue to hold greatest sway, the potential for interactions between human immunodeficiency virus (HIV) infection and other tropical infectious diseases is great.

Such interactions are marked by epidemiologic complexity. The AIDS pandemic is best described as the sum of discontinuous and overlapping epidemics of disease among populations of variable and varying risk (see Chapter 76). The predominant modes of transmission of HIV (perinatal, sexual, and parenteral) result in a bimodal distribution of disease, with peaks among young children and young adults. The risk of infection or disease due to tropical pathogens varies widely with differences in ecological, political, and socioeconomic conditions (including access to medical care); related specific host factors such as age of exposure, pregnancy, behavior, and nutrition; and host genetics. Disease due to a coinfecting pathogen may be due to primary infection, recurrent infection, or the reactivation of latent infection. For some pathogens, the risk factor responsible for the acquisition of HIV may also be the risk factor responsible for the acquisition of the coinfecting pathogen. As a consequence of this epidemiologic complexity, both the prevalence and the expression of coinfection are likely to be variable across ecological, economic, political, behavioral, and cultural divides.

There is also, of course, considerable biologic and clinical complexity in the interaction of agents of tropical diseases

with HIV. Either pathogen has the potential for altering the natural history, immune response, or response to therapy of the other.<sup>3,4</sup>

## EFFECTS OF HIV ON TROPICAL COINFECTIONS

Infection with HIV has the ability to influence the natural history of infection with other pathogens through (1) facilitating infection, (2) altering the incidence of disease by increasing the ratio of disease to infection, (3) changing the presentation of disease, or (4) exacerbating the course of disease.<sup>4</sup> Such effects are presumed to be primarily the result of the immunosuppression associated with HIV infection.

Abnormalities of immune function are found in essentially every cellular and functional compartment of the immune system in AIDS, although profound defects in cell-mediated immunity (CMI) appear to be of greatest clinical importance.<sup>5</sup> In vitro correlates include functional abnormalities of

- CD4+ T cells, with progressive failure of proliferation, interleukin (IL)-2 and interferon- $\gamma$  (IFN- $\gamma$ ) production,<sup>6,7</sup> dysregulated expression of molecules essential for T-cell/antigen presenting cell interactions,<sup>8</sup> abnormal activation-induced apoptosis,<sup>9,10</sup> and expansion of a subset of CD4+ T cells (CD4+CD25+ regulatory T cells) that are potent inhibitors of immune responses both to self and to pathogens<sup>11,12</sup>
- Monocyte/macrophages, with decreased chemotaxis and intracellular microbicidal activity and abnormal cytokine production<sup>5,6</sup>
- Dendritic cells, with reduced ability to present antigen and activate T cells (along with efficient transfer of HIV infection to CD4+ T cells)<sup>13</sup>
- CD8+ T cells, with decreased cytotoxic T-lymphocyte (CTL) function<sup>5</sup> and abnormal activation-induced apoptosis<sup>10</sup>
- Natural killer (NK) cells, with decreased proliferation and IFN- $\gamma$  production<sup>14</sup>

Dysregulation of humoral immunity, marked by polyclonal B-cell activation, is also seen.<sup>5</sup> Functionally, abnormalities of CD4+ T cell, monocyte/macrophage, and dendritic cell function have been thought to be paramount to the suppression of CMI and the opportunistic infections seen in patients with AIDS. In addition to the direct effects of HIV infection, the immune system of HIV-seropositive people may also be compromised in clinically significant ways by profound nutritional and metabolic derangements (e.g., wasting or “slim disease”), therapeutic interventions (e.g., corticosteroids used for the treatment of *Pneumocystis pneumonia*), and the immune abnormalities associated with secondary infections (e.g., the suppression of CMI seen in visceral leishmaniasis).

The list of infectious diseases that are exacerbated by HIV coinfection<sup>5</sup> includes many that are predictable from data demonstrating the important role of CMI in protection from the etiologic agent. Several pathogens for which immunity has been presumed to depend on CMI do not appear to be exacerbated by HIV coinfection, however. The HIV “experiment of nature” has caused a reexamination of the immunology of such “missing infections” in AIDS.<sup>15</sup>

HIV infection can also influence the therapeutic response of patients with presumed tropical infection. The ability to diagnose and monitor coinfection may be compromised by

aberrant serologic responses, including false positives due to polyclonal B-cell activation, false negatives due to blunted antigen-specific antibody responses to newly acquired pathogens in late HIV disease, and false serologic reversion after treatment in late HIV disease.<sup>5</sup> Diagnosis may also be hindered by unusual presentations of disease with coinfecting pathogens. Finally, a plethora of intercurrent pathologic conditions may lead to a dulling of Ockham's razor during the evaluation of disease in AIDS patients. A single pathogen, multiple pathogens, HIV infection, side effects of therapeutic drugs, or a combination of these may be responsible for the presenting complaints. Given the suboptimal response to the chemotherapy of many infections in the presence of profound immunosuppression, drugs may need to be given in greater numbers or for a longer duration. With many pathogens, in the absence of immune reconstitution resulting from highly active antiretroviral therapy (HAART), lifelong suppressive therapy is necessary. Drug therapy in the HIV-infected patient may be complicated further by increased rates of drug allergy as well as by untoward drug interactions in the setting of polypharmacy.<sup>16</sup> Prophylaxis against coinfections may be compromised by substandard vaccination responses.<sup>17–19</sup> Finally, the presence of HIV coinfection can complicate the public health consequences of tropical diseases. AIDS may increase the transmissibility of secondary infections and provide fertile soil for the development of drug resistance. Public health resources devoted to the AIDS pandemic may divert resources away from the control and prevention of other infectious diseases.

The presence of HIV coinfection can lead to disease of markedly greater incidence or severity [the standard definition of an opportunistic infection (OI)]<sup>20</sup> with some tropical infectious diseases, such as leishmaniasis and American trypanosomiasis (Chagas' disease). Coinfection has also been demonstrated to have subtle effects on the course of disease with other tropical agents, such as *Schistosoma mansoni*. No identified alteration has been found in the natural history of many tropical infections, including most nematodes.

With organisms in the latter groups, the current absence of evidence of significant effects of HIV on the expression of disease or the response to treatment should not be construed as strong evidence for the absence of such effects. Most research resources have been spent on understanding the clinical and epidemiologic manifestations of the HIV pandemic in industrialized countries, where tropical infectious diseases are obviously underrepresented.<sup>4,21</sup> Where coinfections with HIV and endemic tropical diseases are marked by low prevalence, subtlety of interaction, diagnostic difficulty, or low research priority, the presence and significance of any interaction are likely to be missed. For example, despite the research priority among tropical infections accorded to malaria, a significant interaction with HIV infection—the lack of a benefit of increasing parity in the control of malaria in pregnant women—was only discovered 15 years after the AIDS epidemic was recognized.<sup>22</sup> With less heavily studied pathogens, comparatively subtle interactions will likely emerge over time as research resources are appropriately directed.

Focusing on OIs may help to highlight some of the clearest data on the clinical expression of AIDS in the tropics. Of the more than 100 agents known to cause OIs in AIDS patients, several are classic tropical pathogens.<sup>20</sup> These are mostly found among the intracellular protozoans, bacteria, and endemic

fungi; there is a marked absence of metazoans. Overall, the clinical expression of AIDS in many resource-poor areas of the tropics appears to involve a different spectrum of OIs than those common in North America and Europe. In place of the high incidences of *Pneumocystis carinii* pneumonia (PCP), disseminated *Mycobacterium avium*, and cytomegalovirus (CMV) found in the resource-rich north, the clinical expression of AIDS in much of the tropics has been marked by frequent tuberculosis (the most common serious AIDS OI in the world), chronic diarrhea, wasting, chronic fever without an obvious localizing source, and pulmonary disease.<sup>23</sup>

The contribution of predominantly tropical pathogens to these latter common syndromes is unclear, which illuminates the problems with much of the available data on HIV disease in the tropics. Understanding the spectrum of AIDS-associated OIs in any given area depends on the presence of adequate surveillance systems, which are often lacking in resource-poor regions of the tropics. In the presence of inadequate infrastructures, limited financial resources, and difficult access to medical care on the part of the socially disadvantaged, surveillance is likely to be sporadic and to involve mainly the sampling of subgroups of AIDS patients at late stages of disease.<sup>21</sup> Where resources are limited, diagnostic reporting is likely to be biased in favor of OIs that are inexpensive to diagnose (or misdiagnose).<sup>21</sup> Even the common impression that the progression of AIDS is more rapid in sub-Saharan Africa than in industrialized countries<sup>24–27</sup> rests on data that are less than robust.<sup>28</sup> A more rapid observed course (presumed due to a higher frequency and virulence of coinfection and problems of nutrition and access to medical care) may represent in large part a systematic bias in favor of later initial diagnosis of HIV infection and AIDS.<sup>21,23</sup> Conversely, it has been suggested that the burden of illness and mortality in early HIV disease (often unrecognized as such) due to high-grade pathogens, such as *Streptococcus pneumoniae*, *Mycobacterium tuberculosis*, and the salmonellae, may rival that due to the OIs of late-stage AIDS in the tropics.<sup>29,30</sup>

HIV has shed light on many previously obscure human pathogens. Some, such as the enteric microsporidians, were unknown as agents of human disease prior to the AIDS epidemic. Others, such as *Cryptosporidium parvum*, were underappreciated as causes of disease in normal hosts until their prevalence in AIDS patients led to systematic study in normal hosts. The list of agents causing OIs in AIDS patients is bound to expand. It is reasonable to expect that tropical regions will be prime locations for the identification of further such agents.

## EFFECTS OF TROPICAL INFECTIONS ON HIV COINFECTION

There are theoretical and experimental reasons to believe that coinfection can significantly alter the course of HIV pathogenesis. The central role of ongoing viral replication in HIV pathogenesis is firmly established, and the set point concentration of plasma viremia correlates well with long-term clinical outcome.<sup>31</sup> It is presumed that any increases in viral replication have the potential for accelerating the course of disease. Efficient replication of HIV in CD4+ T cells is dependent on cellular activation. Similarly, activation of monocyte/macrophages and dendritic cells can stimulate HIV replication by increasing transcription factor binding to the HIV long

terminal repeat region (LTR), enhancing LTR-directed transcription. Coinfecting pathogens can stimulate such immune cell activation either directly (e.g., stimulating signaling through pathogen recognition receptors such as Toll-like receptors<sup>32</sup> or upregulating transcription factor transactivation in coinfecting immune cells) or indirectly (e.g., promoting the generation of proinflammatory cytokines such as tumor necrosis factor- $\alpha$  [TNF- $\alpha$ ] or activating CD4+ T cells as part of the adaptive immune response). Immune activation can also lead to upregulation of the expression of HIV coreceptors,<sup>33</sup> thereby facilitating the infection of fresh cells.

Immunologic responses to pathogens, as well as to purified vaccine antigens, clearly have the potential for enhancing the dynamic burden of HIV replication. In vitro studies with diverse pathogens have provided mechanistic support for this idea.<sup>34–36</sup> Experimental evidence has also suggested that immune activation-driven augmentation of the HIV viral burden can occur in vivo.<sup>37–44</sup> There is also circumstantial evidence that such immune activation may enhance HIV pathogenesis.<sup>45,46</sup> Both points remain somewhat controversial, however.<sup>47</sup> Whether immune activation-related increases in viral load actually accelerate the pathogenesis of HIV may depend on whether the changes are transient (as with immunization or with treated acute infection) or chronic (as with untreated or untreatable infection, or through a resetting of the set point of plasma viremia by a particular coinfection).<sup>48</sup>

Direct equation of immune activation with upregulation of HIV replication is simplistic, however. With CD4+ T cells, the mechanism of activation appears to be critical to whether viral replication is induced or suppressed.<sup>49,50</sup> Furthermore, activation of proinflammatory cytokine production with positive effects on HIV replication goes hand in hand with activation of anti-inflammatory cytokine production that can inhibit HIV replication.<sup>51</sup> More generally, proinflammatory responses reliably induce counterregulatory responses that suppress subsequent immune activation.<sup>52</sup> It thus should not be surprising that in vitro studies have provided mechanistic support for the ability of coinfecting pathogens to suppress HIV replication.<sup>53–56</sup> Indeed, the overall effect of acute coinfection with some pathogens, including measles virus, dengue virus, and *Orientia tsutsugamushi*, may be a decrease in HIV viral load.<sup>57–59</sup>

In addition to the viral sequelae of generalized immunologic activation, induction of specific alterations in the immunoregulatory environment of the host by ubiquitous tropical pathogens has been postulated to accelerate the course of HIV. Cross-regulating subsets of CD4+ T cells have been distinguished by their cytokine profiles and functional activities: Th1 cells (producing IFN- $\gamma$  and IL-2, among other cytokines) are important in classical macrophage activation, the development of CMI, and the generation of humoral responses involving complement-fixing antibody isotypes; Th2 cells (producing IL-4, IL-5, and IL-13, among other cytokines) are important in alternative macrophage activation, the generation of immunoglobulin E (IgE) responses, eosinophilia, mast cell responses, and atopy. The immunologic response to most helminthic parasites is dominated by the production of Th2 cytokines. Evidence from murine systems shows that helminth-driven Th2 polarization can shift the immunologic response to heterologous antigens and pathogens from a Th1- to a Th2-dominant pattern, as well as significantly suppress CD8-mediated viral clearance.<sup>60,61</sup> Such responses

have also been found to impair antigen-specific Th1 immune responses in both mice and humans.<sup>60,62</sup> Helminthic infection is chronic and widespread in the tropics. The resultant Th2 “priming” of the immune system may favor progression of HIV disease.<sup>63</sup> Several mechanisms have been postulated. First, a Th2-polarized immune system may directly suppress CD8 T cell-mediated anti-HIV responses.<sup>61</sup> Second, HIV may preferentially replicate in Th2 cells.<sup>64</sup> Third, T cells from HIV-seropositive people undergo abnormal activation-induced apoptosis,<sup>9,10</sup> which is thought to play a role in the depletion of both CD4+ and CD8+ T cells over time. Th2 cytokines can amplify such activation-induced apoptosis.<sup>65</sup> Fourth, Th2 cytokines can upregulate HIV coreceptor expression by CD4+ T cells and monocyte/macrophages.<sup>66,67</sup> Of note, it has been demonstrated that peripheral blood cells from patients with intestinal helminth infection are more susceptible to in vitro infection with HIV than are cells from helminth-uninfected patients.<sup>68,69</sup>

Although intriguing, the hypothesis that endemic helminth coinfection leads to acceleration of the disease course of HIV remains unproven. A study in Ethiopia indicated that HIV viral load was significantly higher in individuals with various helminthic infections than in individuals without helminths, correlating positively with the parasite load as well as decreasing after elimination of the worms by antiparasitic treatment.<sup>70</sup> However, similar studies performed in Uganda and examining larger numbers of patients convincingly failed to replicate these findings.<sup>71,72</sup> These latter studies strongly suggest that helminth coinfection is not associated with faster progression of HIV disease.

Other effects of coinfection are perhaps more concrete. Tropical diseases may lead directly to an increased risk of infection with HIV. Treatment of the severe anemia induced by malaria has led to the HIV infection of countless children by transfusion.<sup>73</sup> Genital schistosomiasis, like other genital inflammatory conditions, may increase the efficiency of HIV transmission.<sup>74</sup>

## CLINICAL SUSPICION OF COINFECTION

Lewis Thomas wrote that infectious disease “usually results from inconclusive negotiations for symbiosis.”<sup>75</sup> In this light, most tropical pathogens lead to high infection:disease ratios. Whether disease is present or not, sterile immunity is not thought to be achieved after infection with most intracellular protozoans. This is as much the case with the tropical and subtropical agents of leishmaniasis and Chagas’ disease as it is with the ubiquitous agent of toxoplasmosis. These are thus lifelong infections, with serious disease often resulting when an HIV-infected host defaults on his or her side of these immunologic “negotiations.” From the point of view of the clinician in a nonendemic area, this necessitates obtaining a lifetime travel history for all HIV-infected patients. From the perspective of the clinician from either endemic or nonendemic areas, it is equally necessary to have an appropriate index of suspicion for HIV coinfection when contemplating the possibility of a tropical infectious disease. In the process of giving this important virus its diagnostic due, however, it is critical to avoid letting the presence or suspicion of HIV infection distract from the careful consideration of etiologic agents that present and respond similarly in HIV-seronegative and HIV-seropositive people.

The basic biology of HIV; the progression, diagnosis, and treatment of HIV disease; and the epidemiology of HIV/AIDS in the tropics are discussed in Chapter 76. This chapter focuses on the natural history, diagnosis, treatment, and prevention of tropical diseases and OIs in the HIV patient. Distinguishing tropical from other pathogens has its artificial side. Measles, not usually thought of as a tropical disease, causes significant mortality only in the tropics today. Tuberculosis, a pandemic infection, is the principal AIDS-related OI in the tropics. Given the historical preoccupation of the field of tropical medicine with parasitic infections, such infections receive close attention here. For practical reasons, OIs that are common in the industrialized world are not discussed in depth unless there are compelling clinical or epidemiologic reasons for doing so. Multiple references are available via the Internet that discuss these cosmopolitan OIs in detail.<sup>76–79</sup> Further information on all of the specific organisms discussed here can also be found in the relevant chapters of this book.

The diagnostic, prophylactic, and therapeutic recommendations discussed here describe an approach to the HIV patient that is not limited by scarce medical resources. As such, like many strategies for dealing with HIV disease that have evolved in affluent industrialized countries (including HAART, high-technology diagnostics, and multidrug chemoprophylaxis), many of these recommendations may not easily be translated to resource-poor areas of the tropics.

## **PATHOGENS**

### **Protozoan Infections**

#### **Malaria**

Malaria (see chapter 90) remains one of the most important infectious diseases in the world today, causing 100 to 200 million new cases and 1 to 2 million deaths each year. Evidence from both murine and human studies suggests an important role for CD4<sup>+</sup> T cells in protective immunity to blood-stage malaria. With large areas of shared endemicity and prevalence, a medically significant interaction between HIV and malaria was thus expected and feared.<sup>80</sup> Initial studies were negative; falciparum malaria did not appear to be an OI or to accelerate the progression of HIV disease.<sup>80–85</sup> However, follow-up studies have revealed significant bidirectional interactions between *Plasmodium falciparum* and HIV.

HIV replication in peripheral blood cells is enhanced by exposure to *P. falciparum* antigens in vitro, in part through induction of TNF- $\alpha$ .<sup>86</sup> Increased HIV replication in dendritic cells has also been seen after the in vivo infection with *Plasmodium chabaudi* of mice transgenic for the HIV genome in a process that appears to be dependent on CD4<sup>+</sup> T-cell activation.<sup>87</sup> The production of TNF- $\alpha$  during malarial paroxysms,<sup>88</sup> along with the antigenic exposure of parasitemia, might thus reasonably be expected to increase HIV viral load. Indeed, clinical studies from Malawi have shown that *P. falciparum* infection is associated with increased HIV viral burden in peripheral as well as placental blood.<sup>89,90</sup> Treatment was associated with a reduction in viral load, although it remained elevated compared to controls for the 4-week duration of the study.<sup>89</sup> Whether or not malaria-mediated increases in HIV replication accelerate the course of HIV disease remains to be determined.

The first significant clinical effect of HIV on malaria was found in the setting of pregnancy. In areas of high malarial

endemnicity, the high degree of immunity that women of child-bearing age have developed to severe malaria is compromised by pregnancy. The placental vasculature shields parasitized erythrocytes from the systemic immune response, allowing localized erythrocytic replication of the parasite. Placental parasitemia has been associated with low birth weight and, hence, increased infant mortality. Local uteroplacental immune responses do restrict parasite replication, however, and the effectiveness of these local responses increases in subsequent pregnancies under pressure of recurrent malarial exposure. In 1996, a study performed in rural Malawi demonstrated that the beneficial effects (maternal, placental, and neonatal) of parity in the control of parasitemia during pregnancy were markedly attenuated in the face of HIV coinfection.<sup>22</sup> Since then, multiple studies performed in sub-Saharan Africa have probed the effects of coinfection on the outcome of pregnancy.<sup>90–100</sup> Such studies have shown that (1) HIV infection is associated with increased rates and levels of peripheral and placental parasitemia, clinical malaria, and maternal anemia in pregnant women, and (2) coinfection is associated with a higher risk of low birth weight, preterm birth, intrauterine growth retardation, and postnatal infant mortality.<sup>101</sup> Although placental parasitemia is associated with increased placental HIV viral loads in coinfecting patients,<sup>90</sup> it remains unclear as to whether malaria infection increases the risk of mother-to-child transmission of HIV. Conflicting results (enhancement, protection, and no effect) have been published.<sup>96,97,100</sup> A World Health Organization (WHO) technical consultation has recommended that HIV-infected pregnant women who are at risk for malaria should always have protection with insecticide-treated bed nets, along with (according to HIV stage) either intermittent preventive treatment with sulfadoxine/pyrimethamine or daily trimethoprim-sulfamethoxazole (cotrimoxazole; TMP-SMX) prophylaxis.<sup>102</sup>

HIV infection is associated with an increased incidence of parasitemia, the risk of clinical malaria is significantly higher in HIV-infected adults, and this risk increases with decreasing CD4 cell count.<sup>103–105</sup> Notably, HIV infection has also been found to be a risk factor for severe malaria in nonimmune populations (in an area of unstable transmission).<sup>106</sup> Finally, although early studies found no evidence that the treatment or prophylaxis of malaria was altered by HIV coinfection,<sup>81,83</sup> the risk of malaria treatment failure has recently been found to be higher in CD4-depleted HIV positive individuals.<sup>107,108</sup>

HIV protease inhibitors currently used for HAART have understudied interactions with a variety of drugs used for malaria prophylaxis and treatment. A variety of protease inhibitors, as well as the nonnucleoside reverse transcriptase inhibitors delaviridine and efavirenz, inhibit hepatic cytochrome P-450 enzymes. Principal effects are on the CYP3A4 isoform (with ritonavir being the most potent inhibitor), although the CYP2D6 isoform may also be affected.<sup>109,110</sup> Nevirapine and efavirenz cause secondary induction of CYP3A4, an effect of ritonavir and nelfinavir as well.<sup>109,110</sup> Most antimalarial agents are largely metabolized via P-450 enzymes. Mefloquine appears to be no exception, although the details remain poorly understood.<sup>111</sup> Proguanil and chloroquine metabolism appears to be largely by the CYP2C19 and CYP2D6 isoforms, respectively.<sup>112–115</sup> Chloroquine also undergoes appreciable renal excretion, whereas doxycycline largely avoids these pathways in vivo. A detailed understanding of atovaquone metabolism appears to be lacking.

Actual published pharmacokinetic data suggest that (1) there are no significant drug–drug interactions between nelfinavir or indinavir and mefloquine<sup>116</sup>; (2) ritonavir has minimal effects on mefloquine pharmacokinetics, whereas mefloquine suppresses ritonavir plasma levels<sup>117</sup>; and (3) atovaquone increases serum zidovudine (AZT) levels by approximately 30%, although AZT has no effect on the pharmacokinetics of atovaquone.<sup>118</sup> In summary, the actual pharmacokinetics are not easily predictable from theoretical considerations, and there is a paucity of data. Based on the current data, mefloquine, doxycycline, chloroquine, and malarone (atovaquone + proguanil) are likely to be safe and to retain efficacy for prophylaxis of sensitive strains of malaria.

Among other malaria treatment options, quinidine, quinine, and  $\beta$ -artemether are all predominantly metabolized through CYP3A4 isoforms.<sup>110</sup> Large (more than threefold) increases in the area under the curve (AUC) for quinidine are expected for ritonavir.<sup>119</sup> As a result, quinidine has been considered to be contraindicated for those on ritonavir,<sup>119</sup> and this likely applies to quinine as well. There are no actual data, however. Whether there are clinically relevant effects of these protease inhibitors on the metabolism of artemisinin compounds (dependent at least in part on CYP3A4) remains unknown. Uncomplicated malaria can probably be safely treated with chloroquine (if sensitive), pyrimethamine/sulfadoxine, or mefloquine. Use of quinine, quinidine, or artemisinin compounds remains essential for the parenteral therapy of severe chloroquine-resistant malaria. For those on ritonavir (and/or other protease inhibitors, delaviridine, or efavirenz), the normal loading dose of quinine or quinidine should probably be given, along with some reduction of the maintenance infusion dose. Obviously, careful monitoring needs to be done for the potentially fatal arrhythmic consequences of quinine/quinidine overdosage in this setting. Given the lack of data, however, underdosing may also be a potential problem. The “washout” period for the metabolic effects of ritonavir is thought to be 24 to 48 hours.

A higher incidence of allergic responses to sulfonamides makes pyrimethamine–sulfadoxine (Fansidar) less attractive as a malaria therapy in HIV-seropositive patients, at least in North American populations.<sup>120</sup> Furthermore, Stevens–Johnson syndrome and related adverse mucocutaneous reactions to the long-acting sulfa compound, sulfadoxine, have contraindicated its benefits for use in malaria prophylaxis in developed countries.<sup>121</sup>

The presence of HIV infection alters the predictive value of fever in the empirical diagnosis of malaria. In areas with a high prevalence of both HIV and malaria, the common practice of empirically treating febrile adults for malaria leads to gross overestimation and overtreatment of malaria.<sup>103</sup> Finally, treatment of severe anemia due to malaria is one of the most common reasons for blood transfusion in sub-Saharan Africa. Malaria thus provides an indirect but very important risk factor for the acquisition of HIV infection by children where the blood supply is not well screened.<sup>73</sup>

### Babesiosis

The genus *Babesia* contains more than 70 known species of tick-borne intraerythrocytic protozoans that parasitize wild and domestic vertebrates, predominantly in tropical and subtropical areas. Human babesial disease has been reported

mostly from temperate climates (see Chapter 91). A significant clinical interaction with HIV infection has been suggested for *Babesia microti*, raising the possibility that disease with tropical babesial species may be a risk for AIDS patients and providing the rationale for the current discussion. There are five reported cases of babesiosis due to *B. microti* in HIV-infected people.<sup>122–126</sup> Two cases occurred in splenectomized patients; in one, chronic low-level hemolysis due to *Babesia* prior to splenectomy was likely. Patients with intact spleens presented with fevers of unknown origin (FUOs) in the face of CD4 counts less than 200/ $\mu$ L. In one, the FUO lasted for months and was associated with night sweats, dry cough, weight loss, and dyspnea on exertion. Persistent parasitemia after clinically successful chemotherapy led to the need for chronic suppressive therapy. In another patient, recurrent disease led to retreatment 8 months after initial therapy. Quinine plus clindamycin and atovaquone plus azithromycin both have therapeutic efficacy in acute disease.<sup>127</sup> In HIV-infected patients, chronic suppressive therapy appears to be indicated. As with all vector-borne diseases, vector avoidance is the most efficient way to prevent disease. Significant interactions with HIV infection remain to be described for European bovine *Babesia* species (*Babesia bovis* and *Babesia divergens*) and the emerging agents of human babesiosis (WA<sub>1</sub>, CA<sub>1</sub>, MO<sub>1</sub>) in North America.

### Leishmaniasis

With the exception of *Toxoplasma gondii*, *Leishmania* is the most common tissue protozoan causing OI in patients with AIDS (see Chapter 94). This is not surprising because cellular immune responses (in particular, Th1-mediated immune responses) are critical for protection from *Leishmania*. The competence of the Th1 axis of cellular response becomes increasingly compromised during the progression of HIV-related immunosuppression, providing a favorable environment for disease due to *Leishmania* species. Furthermore, in vitro evidence suggests that coinfection of macrophages with HIV and *Leishmania* can directly upregulate parasite replication.<sup>128</sup> In vivo, the overall loss of immunological control of parasite infection is reflected by often aberrant manifestations of visceral leishmaniasis (VL) in AIDS, including peripheral parasitemia (found in more than 50% of coinfecting people) and parasite dissemination to unusual body compartments.<sup>129</sup> An AIDS-related OI occurring at low CD4+ T-cell counts, leishmaniasis may be due either to primary *Leishmania* infection or to the reactivation of clinically latent infection.<sup>130,131</sup> Although the published data on the interaction of HIV and *Leishmania* focus largely on the effects of HIV on leishmanial infection and disease, it should be noted that there is also both in vitro and in vivo evidence that *Leishmania* can augment HIV replication.<sup>132–135</sup>

Although leishmaniasis has a worldwide distribution in the tropics and subtropics, it normally requires an arthropod vector, the sandfly, to move the organism from its sylvatic (zoonotic) cycle to the human host. With certain species of *Leishmania* (*Leishmania tropica* and *Leishmania donovani*) and in some locations (e.g., Syria and India, respectively), an anthroponotic human-to-human cycle via the sandfly can exist. In situations in which intravenous drug use is practiced, transmission is simplified even further by direct person-to-person transfer via contaminated needles and syringes. Generally, however, leishmaniasis is a rural or periurban zoonosis.

The experience with VL complicating HIV/AIDS in Mediterranean countries indicates that many, perhaps most, of the leishmanial infections are acquired with HIV or after HIV infection has already occurred. The transmission of both agents that occurs by sharing of needles and syringes by intravenous drug users could theoretically be reduced by an aggressive program of education and provision of clean needles and syringes. An effective program of sandfly vector control will interrupt transmission from heavily infected human reservoirs to other humans as well as the more usual cycle of infected dogs to humans. Vector control is also the only way to prevent coinfection with *Leishmania* in those who acquire HIV sexually.

From the relatively high prevalence of latent leishmanial infections, it would appear that reactivation of latent infections could account for the increasing numbers of HIV-*Leishmania* coinfections; however, this concept is not always supported by epidemiologic evidence. A greater variability in zymodemes (enzyme markers) has been found in parasite isolates from HIV-infected than -uninfected patients. In one series, five isolates were recovered from HIV-infected patients that had previously not been encountered in immunocompetent people with either VL or cutaneous leishmaniasis (CL).<sup>136</sup> The finding that certain strains of *Leishmania* typically causing cutaneous disease are being recovered from the bone marrow of coinfecting patients could support either the primary or the reactivation hypothesis.<sup>137</sup>

Normally, the age distribution of VL caused by *L. donovani* includes adults as well as children. In contrast, VL due to *Leishmania infantum* affects children predominantly, often age 5 years or younger. In Spain, where intravenous drug use accounts for the majority of HIV-*Leishmania* coinfections, the age distribution of VL has been reversed, with most cases occurring in young adult males.<sup>138</sup> The fact that 50% of coinfecting patients have demonstrable organisms in peripheral blood smears<sup>139</sup> and the fact that sandflies can readily be infected by feeding on coinfecting patients<sup>140</sup> provide evidence for an additional anthroponotic cycle of transmission in this setting.<sup>137</sup> In summary, although reactivation of latent leishmanial infection is difficult to exclude, increasing evidence—in southern Europe, at least—favors primary infection by certain strains of *Leishmania* as the main mechanism for coinfection with HIV/AIDS.

With the spread of the HIV pandemic, there is increasing epidemiological overlap of areas in which HIV and leishmania occur, particularly in eastern Africa, India, Brazil, and Europe. Cases have been reported from approximately 40 countries, although the bulk of cases have been reported from southern Europe.<sup>129–131,137,141,142</sup> Of note, relatively few cases of American mucocutaneous leishmaniasis have been recognized in HIV-infected subjects.<sup>143,144</sup> The propensity for disseminated disease in the presence of HIV appears to be limited to certain species of *Leishmania*. The bulk of the information on VL complicating HIV infection involves *L. infantum* in the Mediterranean region. Presumably, the ability to visceralize under the influence of HIV also applies to *L. donovani* in southern Asia and Africa and to *L. chagasi* in Latin America; however, documentation for this is still somewhat meager, one of the possible reasons being the poor overlap between geographic distribution of leishmaniasis caused by these species and the distribution, as well as prevalence, of HIV infection. The species of *Leishmania* that cause CL have been implicated only rarely as

OIs in HIV/AIDS. In one instance, *L. braziliensis* was recovered from the bone marrow of a patient with a CD4+ T-cell count of less than 10/ $\mu$ L,<sup>145</sup> but the main clinical picture in this case, as well as in others,<sup>146–148</sup> including a patient infected with *Leishmania major*,<sup>149</sup> has been one of multiple cutaneous lesions resembling diffuse CL.

A febrile illness of longer than 2 weeks' duration in an HIV-infected person with a lifetime history of travel to *Leishmania*-endemic regions of the world should certainly raise suspicion of leishmaniasis complicating HIV infection. If the patient is an intravenous drug user, travel to southern Europe, especially Spain, France, and Italy, would be particularly pertinent. Clinical diagnosis of VL in leishmania-HIV coinfecting people may be difficult. Only 75% of HIV-infected patients, as opposed to 95% of non-HIV-infected patients, exhibit the characteristic clinical pattern, namely fever, splenomegaly, and hepatomegaly.<sup>130,131,137,142,150</sup> With increasing immunosuppression, clinically evident ectopic localization of parasites becomes common.<sup>151</sup> Gastrointestinal, laryngeal, pulmonary, and peritoneal involvement has been reported.<sup>151–158</sup> Single and multiple cutaneous forms and/or mucosal and mucocutaneous lesions have also been described in AIDS patients worldwide.<sup>148,153,159</sup>

In immunocompetent people, tests for antileishmanial antibodies have been very useful in the diagnosis of VL because B cell activation is prominent, with large amounts of both specific and nonspecific antibody being produced. In contrast, approximately 50% of coinfecting patients lack detectable antibody levels.<sup>130,131,150,160</sup> The situation may be different in instances in which leishmanial infection has preceded HIV infection and the impaired immune response that ensues. Gradoni and associates<sup>161</sup> suggested that this type of serologic data could be used as an indicator of the sequence of acquisition of the two infections. Support for this concept is provided by a report from Ethiopia of seven cases of VL with HIV coinfection, all with highly elevated antileishmanial antibody titers.<sup>162</sup> All patients had lived for many years in a leishmaniasis-endemic area of Ethiopia.<sup>162</sup> The recombinant antigen rK-39 appears to be highly sensitive and specific for immunodiagnosis of VL due to *L. donovani* and *L. chagasi* in patients without complicating HIV infection; however, the sensitivity of rK-39 for immunodiagnosis of cutaneous cases from Turkey was greatly reduced compared with most cases of VL.<sup>163</sup> The utility of rK-39-based diagnostics is not clear in HIV-seropositive people. The peripheral parasitemia displayed by many HIV coinfecting individuals allows the detection of parasites from the blood in approximately 50% of cases. Cultures and polymerase chain reaction (PCR) of buffy-coat preparations are positive in 70% and up to 100%, respectively.<sup>130,131,164</sup>

There is abundant evidence that successful treatment of leishmanial disease, regardless of the drugs used, ultimately requires intact CMI. The coinfecting patient is the victim of a double insult to the immune system. VL is associated with antigen-specific T-cell unresponsiveness<sup>165</sup> and dysfunctional cytokine responses.<sup>166</sup> This situation is further compounded by the immunologic abnormalities associated with HIV infection.

Therapy for VL in the face of HIV coinfection remains controversial, largely due to a lack of firm data. The same drugs used for treatment of VL in normal hosts (including pentavalent antimonials and amphotericin B preparations) have utility in the treatment of HIV coinfecting patients, albeit

with significantly less efficacy.<sup>150</sup> Amphotericin B is a conventional drug for all forms of leishmaniasis, including visceral disease. Liposomally encapsulated amphotericin has the theoretical advantage of being targeted to monocyte/macrophages, host cells for leishmanial parasites. Between 40% and 65% of coinfecting patients have initial parasitological cure after treatment with pentavalent antimonials, amphotericin B deoxycholate, or amphotericin B lipid complex.<sup>150,167,168</sup> Among these options, treatment with lipid formulations of amphotericin B appears to have similar efficacy, but less severe toxicity, than the other drugs. However, the experience with lipid formulations of amphotericin B in coinfecting patients remains meager.<sup>168</sup> These lipid formulations are also quite expensive. Trials aimed at optimizing the therapy of VL in AIDS are clearly needed.<sup>168</sup> Even with initial cure, relapse is predictable over time, occurring in up to 80% of coinfecting individuals within 1 year.<sup>150,167,169</sup> The optimal drug for secondary prophylaxis remains unclear. Pentamidine given once every 3 or 4 weeks<sup>170</sup> and liposome-encapsulated amphotericin every 2 weeks<sup>171</sup> or 3 weeks<sup>169</sup> have been used for secondary prophylaxis.

Miltefosine, an oral agent that is safe and effective for the treatment of Indian patients with VL,<sup>172</sup> has shown some promise in early compassionate-use treatments for VL in HIV-infected subjects.<sup>173</sup> Further optimization of treatment and suppressive regimens of miltefosine in HIV patients may establish roles for this new antileishmanial agent for therapy and suppressive prophylaxis of VL in HIV-infected patients.

The fact that significant reductions in the incidence of AIDS-related VL have been seen in southern Europe after the advent of HAART,<sup>174,175</sup> along with the fact that HAART-related immune reconstitution has allowed the discontinuance of secondary prophylaxis for other OIs, has raised hope that HAART will allow for safe discontinuance of secondary prophylaxis for VL. Details of the levels of immunological and virological responses needed for termination of such secondary prophylaxis remain to be determined.<sup>176–178</sup>

### American Trypanosomiasis (Chagas' Disease)

American trypanosomiasis, or Chagas' disease (see Chapter 93), is a well-recognized OI in AIDS.<sup>179</sup> The causative organism, *Trypanosoma cruzi*, and the blood-sucking vector (triatomine) bugs that transmit this protozoan are restricted to the Western Hemisphere but are widely distributed from the United States to Chile and Argentina. Because the HIV-related Chagas' disease reported to date largely represents reactivation of chronic infection during the course of HIV-induced immunosuppression and not primary infection in the face of AIDS (which is not surprising given the differing patterns of epidemiological risk for these infections: largely rural for *T. cruzi* and largely urban for HIV), this OI can be expected to appear outside these geographic bounds. It should be noted that activation of latent *T. cruzi* infection, as well as exacerbated primary infection (transmitted by blood transfusion), is also well described in the face of the iatrogenic immunosuppression used for solid organ transplantation and therapy for hematological malignancies.

Available data suggest that clinical *T. cruzi* reactivation in the face of HIV coinfection occurs largely in those with CD4+ T-cell counts less than 200/ $\mu$ L. Clinically, such reactivation most commonly involves the central nervous system.<sup>179,180</sup> *Trypanosoma cruzi* was probably late in being recognized as an opportunistic pathogen in those with HIV infection because

the most prominent features of central nervous system disease are similar to those of toxoplasmic meningoencephalitis. Enlargement of hemorrhagic foci can produce mass effects simulating brain tumors. Lesions are often multiple, with computed tomographic (CT) scans and magnetic resonance imaging (MRI) showing ring enhancement and preferential involvement of the white matter. Toxoplasmic encephalitis may also be present in the same patient.<sup>181</sup> The cerebrospinal fluid (CSF) findings include a slight pleocytosis, increased protein, slightly decreased glucose in some patients, and the presence of trypanosomes. Histologically, the brain lesions show necrotic foci with hemorrhage and infiltration of inflammatory cells. Amastigote forms of the parasite are abundant in glial cells and macrophages and only occasionally in neuronal cells. Myocarditis is a common autopsy finding in those dying of AIDS-related *T. cruzi* meningoencephalitis.<sup>178</sup> Such myocarditis is often clinically silent. Clinical manifestations, when present, involve arrhythmias and congestive heart failure.<sup>179,182,183</sup> Correct diagnosis of reactivated *T. cruzi* infection depends, first, on considering the possibility based on the geographic origin of the patient and on an appreciation of the clinical picture. If neurologic signs are present, performing a CT scan or MRI is key.<sup>184</sup> The imaging pattern of central nervous system (CNS) *T. cruzi* infection is indistinguishable from that of toxoplasmic encephalitis. Direct microscopic examination of centrifuged sediment of CSF will often show motile trypanosomes. If fever and other systemic signs are present, direct examination of the buffy coat from the microhematocrit tube may also show motile trypanosomes. Since serum antibodies to *T. cruzi* indicate previous infection with the parasite, this test is only useful for ruling out reactivated infection if it is negative. If other tests are inconclusive, biopsy of a brain lesion to demonstrate characteristic organisms can be done. PCR on blood or CSF requires research laboratory facilities.

Clinically, differentiating HIV-related reactivation of Chagas' disease reactivation from chronic chagasic disease may be difficult. HIV-related reactivation is associated with high parasitemia, however, whereas the parasitemia of chronic disease is very low.<sup>185</sup> Indeed, even in the absence of overt, clinical reactivation, chronic Chagas' disease is associated with a higher percentage and level of parasitemia in those coinfecting with HIV (independent of CD4 count) than in HIV seronegatives.<sup>186</sup> The effects of coinfection appear to be bidirectional. HIV viral load was carefully documented to increase simultaneously with an asymptomatic increase in *T. cruzi* parasitemia, subsequently returning to baseline in the face of successful antiparasitic treatment.<sup>187</sup> Nifurtimox and benznidazole, both of which have moderate antitrypanosomal activity, are the standard drugs recommended for treatment of Chagas' disease. There simply is not enough experience to evaluate the effectiveness of these drugs in the treatment of *T. cruzi* infections complicating HIV or AIDS, especially in cases with meningoencephalitis. No information is available on the penetration of these drugs into the CNS, and the survival time of reported cases of coinfection has been short. A patient reported by Nishioka and coworkers<sup>188</sup> survived for 92 days, with disappearance of trypanosomes from the blood and CSF as well as clearance of a brain lesion while being treated with benznidazole at a dose of 8 mg/kg/day for 80 days. Clinical improvement and reduction in size of a brain lesion were attributed to treatment with benznidazole plus, later, itraconazole and fluconazole in another patient with coinfection who survived for at least

6 months.<sup>189</sup> Although there is no other reported experience with the use of itraconazole or fluconazole in the treatment of American trypanosomiasis in humans, itraconazole was reported to be very effective in experimental infections.<sup>190</sup> Infected mice given as little as 15 mg/kg/day were protected against death, and concentrations of itraconazole as low as 0.001 µg/mL inhibited replication of the parasites in macrophages. It has been recommended that treatment of *T. cruzi* infection in HIV-positive individuals be started early in the reactivation process, when parasitemia is detectable, but before irreversible end-organ damage has occurred.<sup>187</sup> Such a strategy would hinge on serological identification of those at risk, something indicated in all HIV-infected individuals with appreciable risk of *T. cruzi* infection. Although data are lacking, it should be noted that immunological reconstitution through HAART therapy is likely to provide considerable prophylactic and therapeutic benefit in this disease.

### African Trypanosomiasis

No significant interactions between the agents of African trypanosomiasis (see Chapter 92) and HIV have been delineated. Although T cell and macrophage responses are not thought to be important in the protective host response to trypanosomiasis, trypanosomiasis can suppress cellular immune responses, so a biologic interaction between the two is plausible. No significant epidemiologic association between *Trypanosoma brucei gambiense* and HIV has been found.<sup>191–194</sup> Whether HIV alters the clinical course of either West or East African trypanosomiasis is unclear.<sup>193</sup> There is anecdotal evidence that HIV may complicate the therapy of West African trypanosomiasis, however. Of 18 patients treated with melarsoprol in a rural hospital in the Congo, all 14 HIV-negative patients recovered, whereas 3 of 4 HIV-positive patients died during treatment (likely due to treatment-related encephalopathy) and the fourth failed to respond to therapy.<sup>195</sup>

### Other Trypanosomatids

In addition to the two genera, *Leishmania* and *Trypanosoma*, known to cause disease in humans, the Trypanosomatidae family includes other genera of protozoa that parasitize other vertebrates, insects, and plants. There have been three reports of HIV-infected individuals presenting with symptoms typical of visceral leishmaniasis in which ultrastructural, isoenzyme, and/or kinetoplast DNA analyses of the isolated lesional parasites have indicated that the responsible organism actually belongs to one of these latter genera.<sup>196</sup> The strong implication is that HIV-related immunosuppression can render humans vulnerable to normally nonpathogenic lower trypanosomatids.

### Toxoplasmosis

*Toxoplasma gondii* is a ubiquitous parasite of mammals throughout the world (see Chapter 97). Latent infection lasts for the lifetime of the host. Maintenance of latency is dependent on CMI responses. Reactivation of latent infection is common with increasing immunosuppression in AIDS. The principal manifestation of such reactivation, toxoplasmic encephalitis (TE), is thus a common OI in AIDS patients throughout the world.

The incidence of TE is proportional to the prevalence of latent infection in the population at risk of or with AIDS.<sup>197</sup> In the United States, the rate of latent infection varies between 10% and 40%; in Paris, the rate is 90%.<sup>197</sup> Acquisition of *Toxoplasma* infection is age dependent, but there is wide variation in infection rates even over narrow geographic areas.<sup>198,199</sup> Prevalence rates in the tropics vary from 0% to 90%, with most measured communities falling in a broad middle range.<sup>200–206</sup>

In the United States, prior to the advent of HAART, one-third of *Toxoplasma*-seropositive AIDS patients developed TE in the absence of prophylaxis,<sup>207</sup> 90% of such cases were in patients with less than 200 CD4+ T cells/µL and 70% in those with less than 100 CD4 T cells/µL.<sup>208</sup> The prevalence of TE in AIDS patients in the tropics is unclear, but the burden is thought to be immense and underdiagnosed. Autopsy series that have included examination of the brain have suggested disease prevalence rates in late-stage AIDS patients of 15% in Abidjan, Côte d'Ivoire,<sup>209</sup> 25% in Mexico City,<sup>210</sup> and 36% in Kampala, Uganda.<sup>211</sup>

The presumptive diagnosis of TE is based on clinical presentation, positive *Toxoplasma* serologies, and characteristic neuroradiologic features.<sup>212</sup> A final clinical diagnosis is made based on the clinical and radiographic response to specific chemotherapy. Less common manifestations of toxoplasmosis in AIDS include pneumonia, retinochoroiditis, myocarditis, orchitis, and gastrointestinal involvement. The reader is referred to one of many excellent reviews on *Toxoplasma* in AIDS for information on the clinical management of this cosmopolitan OI.<sup>76–79</sup>

Five percent of TE occurs not as reactivation but as an acute infection.<sup>207</sup> Preventing the transmission of *T. gondii* to *Toxoplasma*-seronegative, HIV-infected people has two facets: (1) avoiding the ingestion of tissue cysts of other intermediate mammalian hosts (i.e., cooking meat well) and (2) avoiding the oocysts of the definitive host, the cat. Avoiding cat feces in and around dwellings is probably not sufficient because the oocysts are viable for up to 18 months in moist soil. Contamination of fresh vegetables may be a common method of human infection, and such foodstuffs should probably be washed well or cooked or both.

Primary prophylaxis (TMP–SMX is preferred)<sup>213</sup> should be taken by all *Toxoplasma*-seropositive HIV patients with a CD4+ T-cell count less than 100/µL. It is safe to discontinue both primary and secondary prophylaxis after HAART-related immune reconstitution (sustained CD4+ T-cell counts >200/µL).<sup>76–79</sup>

### Free-Living Amebae

Free-living amebae of the *Acanthamoeba* and *Balamuthia* genera (see Chapter 95) are rare causes of opportunistic encephalitis and cutaneous disease in late-stage AIDS. Most case reports have been from the United States, but the worldwide environmental distribution of these ubiquitous protozoans and the fact that diagnosis is often postmortem suggest that underdiagnosis is widespread in the tropics and elsewhere.

Granulomatous amebic encephalitis (GAE), a subacute to chronic disease of compromised hosts caused by multiple species of *Acanthamoeba* as well as *Balamuthi mandrillaris*, generally causes death in weeks to months. Clinical and pathologic data, as well as animal models, suggest that the pathogenesis of GAE involves hematogenous dissemination to

the brain from initial upper or lower respiratory (or perhaps cutaneous) sites of infection.<sup>214</sup> Pathologic changes, in the form of necrotizing granulomatous inflammation, are found predominantly in the posterior neuraxis.

*Acanthamoeba* and *Balamuthia* have been isolated from soil, water (including tap water, bottled water, chlorinated pools, and natural sources of fresh- and seawater), and air throughout the world.<sup>215</sup> The isolation of *Acanthamoeba* from the nasopharynx of healthy adults indicates that these organisms may be a common constituent of normal flora.<sup>216</sup> Cellular immunity, along with antibody and complement, appears to be critical to protective immunity to *Acanthamoebae*.<sup>217</sup> Invasive disease occurs in the immunocompromised and debilitated.<sup>214</sup> Occasionally, encephalitis with *Balamuthia mandrillaris* has occurred in apparently normal hosts.<sup>218,219</sup>

More than 20 cases of GAE have been reported in AIDS patients.<sup>214,220–229</sup> Implicated *Acanthamoeba* organisms include *Acanthamoeba castellanii*, *Acanthamoeba culbertsoni*, *Acanthamoeba polyphaga*, *Acanthamoeba rhysodes*, and *Acanthamoeba divionensis*. Disseminated cutaneous disease [subacute granulomatous dermatitis (SGD)] has been a feature of many of these cases and has preceded clinical cerebral involvement by weeks or months in some. SGD has been the sole manifestation of invasive disease in some patients.<sup>230–234</sup> Reported CD4+ T-cell counts have been less than 250/ $\mu$ L (median, 24/ $\mu$ L) at the time of presentation. Where CD4 counts have not been reported, the histories reveal clinical evidence of late-stage AIDS.<sup>214,234</sup>

GAE in AIDS patients is marked by a more rapid course (with death in 3 to 40 days)<sup>214</sup> and a paucity of well-formed granulomas in comparison to other hosts with the disease.<sup>214,233</sup> Symptomatic involvement of the nasopharynx, paranasal sinuses, or the skin prior to development of GAE is common in AIDS patients.<sup>214</sup> Cutaneous lesions are usually nodular, with subsequent enlargement, ulceration, and metastatic spread. Such lesions can be quite pleomorphic (pustules, plaques, eschars, and cellulitis), however, and have been confused with cat-scratch disease, cryptococcosis, sporotrichosis, bacillary angiomatosis, mycobacterial infections, and vasculitis.<sup>214</sup> The most common presentation of cerebral disease is that of fever and headache.<sup>214,232</sup> Focal neurologic deficits and profound changes in mental status are also frequent. Neuroradiologic findings mimic those of toxoplasmic encephalitis, with multiple enhancing mass lesions and surrounding edema. CSF findings are quite variable.<sup>214,232</sup>

A high index of suspicion and tissue or microbiologic diagnosis is key to the antemortem identification of disseminated *Acanthamoeba* infection. Wet mounts of CSF are occasionally useful. Both trophozoites and cysts can be found in tissue biopsies. Cysts have been mistaken for the sporangia of *Rhinosporium* or *Prototheca* or for cryptococci; trophozoites have been mistaken for tissue macrophages.<sup>214</sup> *Acanthamoebae* can be isolated by culture on *Escherichia coli*-seeded non-nutrient agar or in tissue culture medium.<sup>214,232</sup> Identification of species (and even differentiation of *Acanthamoeba* from *Balamuthia*) is not possible morphologically. Immunofluorescence techniques can differentiate *Acanthamoeba* to the group level in tissue section or with cultured organisms. Treatment of disseminated disease due to these organisms is difficult. No chemotherapeutic regimen is clearly efficacious. Agents with possible clinical utility in combination therapy

include pentamidine, 5-fluorocytosine, sulfamethazine, sulfadiazine, fluconazole, itraconazole, ketoconazole, macrolides, phenothiazines, and rifampin.<sup>214,228,229,231</sup> There may be value in testing clinical isolates for drug sensitivities. With isolated cerebral lesions, there may be a role for surgical excision.<sup>229</sup>

In a possible foreshadowing of a newly emerging OI, a case of primary amebic meningoencephalitis due to an apparently newly recognized ameba and not associated with thermally polluted water was reported in a patient with late-stage AIDS in Spain.<sup>235,236</sup>

### Enteric Coccidiosis (*Isospora*, *Cryptosporidium*, and *Cyclospora*)

A trio of coccidian protozoa—*Isospora belli*, *Cryptosporidium* spp., and *Cyclospora* (*Eimeria*) *cayetanensis*—are all prominent causes of self-limited, small bowel diarrhea in immunologically normal hosts as well as causes of chronic, severe disease in the face of HIV coinfection. All are cosmopolitan infections. Infection with a fourth organism, *Sarcocystis hominis*, responsible for both enteric and disseminated coccidiosis in humans, does not appear to have been reported in HIV-infected individuals.

***Cryptosporidium* spp.** (see Chapter 88). In addition to the most common human pathogen *Cryptosporidium hominis* (previously *Cryptosporidium parvum* human genotype, or genotype 1), a variety of zoonotic species also infect humans, including *Cryptosporidium parvum* (previously bovine genotype, or genotype 2), *Cryptosporidium canis*, *Cryptosporidium felis*, *Cryptosporidium meleagridis*, and *Cryptosporidium muris*.<sup>237–239</sup> Zoonotic species may cause more severe human disease and may occur more commonly in immunocompromised people. Because of the high prevalence of disease and the lack of effective specific treatment, cryptosporidiosis is a particularly common and severe problem as an OI throughout the world. Chronic infection and disease are most frequent with CD4+ T cell counts less than 180/ $\mu$ L<sup>240</sup> and are associated with increased mortality.<sup>241–243</sup> The use of HAART therapy has led to a decreasing prevalence of cryptosporidial disease in HIV-infected individuals.<sup>244,245</sup>

Four clinical syndromes of cryptosporidial diarrheal disease in patients with AIDS have been limned: chronic diarrhea (36%), cholera-like disease (33%), transient diarrhea (15%), and relapsing illness (15%). The severe end of the spectrum is seen largely in those with CD4+ T-cell counts less than 180/ $\mu$ L.<sup>246,247</sup> Less commonly, extraintestinal sites are secondarily involved, including biliary tract, stomach, pancreas, lung, paranasal sinuses, and middle ear.<sup>246–249</sup> Of these, biliary tract involvement (presenting with right upper quadrant pain, nausea, vomiting, and fever) represents the most common, clinically important site, being found in up to one-fourth of patients with AIDS-related intestinal disease prior to the use of HAART.<sup>250</sup> Individuals with CD4+ T-cell counts less than 50/ $\mu$ L are at a particular risk for development of symptomatic biliary disease.<sup>250</sup>

No antimicrobial agent has demonstrable, consistent efficacy in HIV-related cryptosporidiosis. Immune reconstitution with HAART should be pursued.<sup>251,252</sup> If HAART fails or is not available, a variety of antimicrobial agents (including nitazoxanide, azithromycin, paromomycin, and atovaquone) may be tried. Supportive treatment with fluids, nutrition, and antimotility agents plays an obvious therapeutic role.<sup>76–79</sup>

***Isospora belli*** (see Chapter 88). Disease due to *Isospora* is less cosmopolitan than that due to *Cryptosporidia*, being most common in tropical and subtropical areas.<sup>253</sup> Isosporiasis usually presents with chronic watery diarrhea and weight loss, with or without vomiting, abdominal pain, and fever.<sup>254</sup> Invasion of gallbladder tissue, similar to that described with *Cryptosporidium*, has been described, along with disseminated involvement of mesenteric and tracheobronchial lymph nodes, in the setting of HIV coinfection.<sup>254,255</sup> Prominent tissue eosinophilia of the involved lamina propria is often present.<sup>253</sup> Diagnostic and therapeutic issues are covered in Chapter 88. TMP-SMX provides effective therapy.<sup>256</sup> Pyrimethamine (with leucovorin) provides a second option.<sup>257</sup> Clinical response is usually rapid, but relapses are common. In the absence of immune reconstitution, suppressive therapy is indicated.<sup>76-79</sup>

***Cyclospora (Eimeria) cayetanensis*** (see Chapter 89). The clinical picture of enteric infection with *C. cayetanensis* in AIDS appears to be similar to that due to other coccidia.<sup>258</sup> It is of interest that biliary tract involvement—as evidenced by right upper quadrant pain, elevated alkaline phosphatase, and thickened gallbladder by ultrasound—has also been described in *Cyclospora* infection.<sup>259</sup> Thus, all three of the enteric coccidia of humans are capable of invading the gallbladder. Diagnostic and therapeutic issues are covered in Chapter 89. As with isosporiasis, cyclosporiasis in AIDS is treatable with TMP/SMX.<sup>258</sup> Subsequent suppressive therapy is indicated.<sup>76-79</sup>

### Microsporidiosis

Microsporidia are intracellular protozoans that, due to HIV and AIDS, have emerged from their relative obscurity as pathogens of insects, fish, and laboratory animals to occupy a new role as important OIs of humans. These cosmopolitan emerging pathogens of the immunosuppressed (including *Enterocytozoon bienusi*, *Enterocytozoon [Septata] intestinalis*, *Enterocytozoon cuniculi*, *Enterocytozoon hellem*, as well as pathogens from several other genera) are considered in Chapter 96.

### Other Protozoan Infections

***Entamoeba histolytica***. This intestinal parasite (see Chapter 86) was initially associated with HIV because of its high prevalence in men who have sex with men (MSM). Despite considerable evidence that immunity in amebiasis requires the participation of CMI, there is no evidence that patients with HIV infection or AIDS are more likely to develop invasive disease.

***Giardia lamblia***. As with *E. histolytica*, a high prevalence of infection with *G. lamblia* (see Chapter 87) was found in the 1980s among MSM.<sup>260</sup> A study of MSM performed at that time revealed no increased prevalence or severity of giardiasis in patients with AIDS.<sup>261</sup> Since then, no evidence has been found of a significant effect of HIV coinfection. Although some studies have indicated a higher prevalence of giardiasis in HIV seropositives, this has not been a consistent finding. Therapy of giardiasis in people with AIDS is usually successful. Some patients, immunocompromised as well as immunocompetent, are refractory to standard therapeutic regimens for giardiasis. It may well be that such refractoriness to standard therapy is found more commonly in the face of HIV coinfection.<sup>262</sup>

***Blastocystis hominis***. Controversy continues to exist as to the role of this organism as a cause of diarrheal disease in

either immunocompetent patients or HIV-infected people.<sup>263</sup> *Blastocystis hominis* has a cosmopolitan distribution; there is no association with the tropics.

***Balantidium coli***. No information is available as to whether this organism can serve as an OI in HIV-infected people.

## Helminthic Infections

### Trematodes

There is no evidence that any trematode infection is more severe or difficult to treat in HIV-infected people. More subtle interactions have been explored in schistosomiasis (see Chapter 116). Study of car washers working on the shores of Lake Victoria in Kenya, a population with a high intensity of exposure to *S. mansoni* and an HIV seroprevalence of approximately 30%, has provided insights into the bidirectional effects of coinfection.<sup>264</sup> The CD4+ T cell-dependent granulomatous response to schistosome eggs has been shown to be important in egg migration from venules to the lumen of the intestine in mouse models of disease.<sup>264</sup> As might thereby be expected, a significant suppression of egg excretion efficiency, controlled for the degree of infection, was found in *S. mansoni*-infected patients in the presence of HIV coinfection and low CD4+ T-cell counts.<sup>265</sup> Although successful therapy of *S. mansoni* infection with praziquantel may depend on the host antibody response, praziquantel was efficacious in treating schistosomiasis in this HIV-infected cohort.<sup>266</sup> Given that schistosome infection likely preceded HIV infection in these individuals, whether praziquantel will have equal efficacy in individuals infected with HIV first remains an open question. Notably, despite similar responses to therapy, individuals with HIV coinfection and low CD4+ T cell counts showed increased susceptibility to reinfection after therapy,<sup>267</sup> a response that appears to correlate with blunted immunological responses to successful drug therapy (and the resultant release of parasite antigen) in such individuals.<sup>268</sup> A study of HIV/*S. haematobium* coinfection in Zambia led to findings that mirror these findings with *S. mansoni*: (1) Coinfected individuals had lower egg excretion, and (2) praziquantel retained efficacy in the face of HIV coinfection.<sup>269</sup> No alteration in resistance to reinfection with *S. haematobium* was seen in the face of HIV infection, but CD4+ T-cell counts were not performed in this cohort lacking evident HIV-related disease. It thus remains possible that, as with *S. mansoni* infection, resistance to reinfection with *S. haematobium* is decreased with progression of HIV/AIDS.

As for effects of schistosomiasis on HIV, there is evidence suggesting that genital schistosomiasis due to *S. haematobium* infection is a risk factor for HIV transmission.<sup>269-271</sup> As with a variety of sexually transmitted diseases, the mucosal (vulval, vaginal, and cervical) inflammatory lesions associated with female genital schistosomiasis are likely to compromise the antiviral barrier of the mucosa, provide a cellular milieu that allows for efficient viral transmission and replication, and enhance viral shedding.<sup>270,271</sup> Correspondingly, male genital schistosomiasis is also likely to be associated with an increased risk of HIV transmission. In Madagascar, *S. haematobium* caused inflammation of the prostate and of the seminal vesicles in most adolescent and adult male patients.<sup>272</sup> By analogy to bacterial urethritis, such chronic inflammation is likely to be associated with increased viral shedding in the semen in HIV-coinfected individuals.

Schistosomiasis is a prime example of a chronic tropical infection that has been postulated to enhance the pathogenesis of HIV. *Schistosoma mansoni* infections act as powerful inducers of Th2 polarization in both murine models and humans.<sup>60–62</sup> The type 2 cytokine environment induced by *S. mansoni* eggs can significantly suppress CD8 T cell–mediated viral clearance in experimental models<sup>61</sup> and has been found to impair antigen-specific Th1 immune responses in both mice and humans.<sup>61,66</sup> Type 2–dominant immunologic responses have also been postulated to favor HIV progression due to preferential replication of HIV in Th2 cells,<sup>64</sup> amplification of activation-induced apoptosis in lymphocytes by type 2 cytokines,<sup>9,10</sup> and upregulation of expression of the HIV coreceptors CCR5 and CXCR4 by CD4+ T cells and monocyte/macrophages.<sup>66,67</sup> Finally, the antigenic exposure of schistosomiasis may lead to sustained upregulation of HIV replication via the effects of chronic immune activation.<sup>60</sup> These considerations remain theoretical. Indeed, treatment of *S. mansoni* infection does not appear to reduce plasma HIV load in coinfecting individuals.<sup>273,274</sup>

### Cestodes

A few unusual manifestations of cestode infection have been reported in AIDS patients. A rapidly expanding, invasive, and ultimately lethal abdominal mass in a patient with a CD4+ T-cell count less than 100/μL was found by ribosomal DNA amplification and sequencing to be due to an as yet uncharacterized cestode.<sup>275</sup> Whether this represents merely the fortuitous concurrence of an unusual pathologic finding with dramatic improvements in diagnostic technology (previous rare cases in normal hosts having occurred in the absence of diagnosis) or the recognition of a new disease because its expression is facilitated or dependent on immunosuppression (AIDS patients serving as “sentinel chickens” for the population at large) is unclear. The latter interpretation is favored by a previous similar case report of presumably disseminated cestode infection in the face of immunosuppression due to Hodgkin’s disease and its therapy.<sup>276</sup>

Four cases of exuberant subcutaneous disease due to the larval form of *Taenia crassiceps* have been reported in AIDS patients.<sup>277–280</sup> As this bests by one the previous number of case reports of human infection with *T. crassiceps*, the suggestion is that HIV infection is a risk for disease with this cestode. A case of hepatic alveolar echinococcal disease in a 6-year-old child with AIDS has been described.<sup>281</sup> Uncommon features of this case include the remarkably young age and hence short incubation period for disease and the complete lack of demonstrable parasite-specific humoral or cellular immune responses.

Finally, 10 cases of neurocysticercosis have been reported in HIV-infected patients,<sup>282–286</sup> a number that is sure to increase given the increasing rates of HIV infection in endemic areas. The frequency of giant cysts and racemose forms of disease is remarkably elevated in these reported cases, again perhaps a reflection of the role of CD4+ T cells in tissue immunity to *T. solium*. Further clinical data on the interaction between HIV and cestode infections are awaited.

### Nematodes

***Strongyloides stercoralis*.** The only nematode implicated as a cause of an OI in the presence of HIV coinfection is the intestinal parasite, *Strongyloides stercoralis* (see Chapter 111).

*S. stercoralis* appeared to qualify as an OI because it is one of the few nematodes capable of actually multiplying in, especially immunocompromised, human hosts. *Capillaria philippinensis*, for which humans are not the natural host, can also multiply internally, but *C. philippinensis* is rare, quite limited in its geographic distribution, and has not been reported as a coinfection in HIV-seropositive people (see Chapter 106).

One way in which immunosuppression enhances *Strongyloides* infection is by permitting or stimulating an increased degree of the normal process of autoinfection.<sup>287</sup> In this process, first-stage rhabditiform larvae (L1) produced by the adult female worm in the upper small bowel are transformed into infective filariform larvae (L3) that can reinvade the intestinal wall of the colon or the perianal or perineal areas. Massive upregulation of the autoinfective process results in the hyperinfection syndrome, with the development of many more adult worms, and the production of large numbers of larvae that disseminate to all organs. The clinical picture is dominated by gram-negative bacterial sepsis, meningitis, or pneumonia.

Hyperinfection is usually associated with immunosuppression, particularly the administration of corticosteroids. In fact, the list of immunosuppressive diseases, both malignant and benign, associated with hyperinfection is unified by having corticosteroids as a common denominator of treatment,<sup>287</sup> but steroids do much more than alter T-cell function, both in the host and in the organism. The defense mechanisms necessary for control of *S. stercoralis* in humans have not been identified. Even direct effects of steroids on the female worms’ reproductive efficiency have been postulated.<sup>287,288</sup> The data are meager.

*Strongyloides* was initially designated as an AIDS OI on its past record of causing hyperinfection in the immunosuppressed.<sup>289</sup> Five years later, when it became apparent that hyperinfection syndrome was not being encountered frequently in patients with AIDS, it was removed from the list of OIs indicative of AIDS.<sup>290</sup> Given the low but appreciable rate (3.9%) of strongyloidiasis among men attending a venereal disease clinic in New York City in 1981,<sup>291</sup> the AIDS epidemic in the United States that developed in the 1980s should have provided some clinical evidence of any predisposition of AIDS patients to hyperinfection. This did not occur. The available evidence makes it extremely unlikely that misdiagnosis or underreporting are the relevant factors here; severe strongyloidiasis or hyperinfection syndrome has prominent clinical features and is often fatal if untreated, and it is not likely that the association would escape notice. Few cases of hyperinfection syndrome have been reported in the English-language literature.<sup>292–301</sup> Even among these cases, the presence of hyperinfection is poorly documented in many.

Diagnosis of (as opposed to suspicion of) hyperinfection syndrome depends on the demonstration of markedly increased numbers of filariform larvae in the stool or multiple such larvae in the sputum. The mere presence of filariform larvae in the sputum only indicates the existence of autoinfection. (It should also be noted that the presence of rhabditiform larvae in the sputum points to neither autoinfection nor hyperinfection but to the presence of adult female worms in the lung.) Unfortunately, confusion of gastrointestinal disease with hyperinfection syndrome is embedded in the literature.

It is possible that the frequency of severe strongyloidiasis complicating HIV infection is much higher in certain areas of

the tropics where both infections are prevalent and medical facilities are lacking; however, an absence of such an association has been noted from just such areas.<sup>15</sup> Petithory and Derouin<sup>302</sup> pointed out that clinical studies of AIDS patients in central Africa, where the prevalence of strongyloidiasis varies from 26% to 48%, did not mention extraintestinal strongyloidiasis. Similarly, a report from Brazil estimated a 1% or 2% prevalence of *Strongyloides* infection in the population of São Paulo, finding the parasite in 10% of 100 AIDS patients, who showed no evidence of systemic strongyloidiasis.<sup>303</sup> Similar results have been found in Zambia.<sup>304,305</sup> A survey of urban adults in Kinshasa (Congo, formerly Zaire) detected *S. stercoralis* in 20% by intensive fecal examinations of single specimens, and it estimated a 50% infection rate in the same population on the basis of positive serologies. There were no significant differences in infection rates in those seropositive or seronegative for HIV (F. Neva, unpublished observations).

Taken together, these data suggest that the presence and severity of clinical disease due to *S. stercoralis* are not significantly increased in patients with HIV infection or AIDS alone. A recent study has shed light on the subject.<sup>306</sup> Careful quantitation of the numbers and proportions of free-living adult worms and directly developing L3 larvae in stool cultures revealed a surprising negative correlation between CD4+ T-cell count and the proportions of adult worms in individuals infected with HIV. Thus, advancing immunosuppression due to HIV is associated, paradoxically, with suppression of the direct development of L3 larvae.<sup>306</sup>

More subtle interactions, such as an increased mean gastrointestinal parasite burden or slower response to therapy, may have been missed. Also, some conditions that cosegregate with HIV/AIDS are known to predispose to the hyperinfection syndrome, including the use of steroids (given for pneumocystis pneumonia and lymphoma in AIDS), inanition (seen in patients with chronic diarrhea, untreated oropharyngeal or esophageal candidiasis, and slim disease), and coinfection with human T-cell lymphotropic virus type I (HTLV-I; see Chapter 76). Strongyloidiasis is an important OI in individuals infected with HTLV-I, and *Strongyloides* infection has been suspected to be a cofactor in the development of acute T-cell leukemia and tropical spastic paraparesis in asymptomatic carriers of HTLV-I.<sup>307,308</sup> Notably, intravenous drug use is a risk factor for infection with both HTLV-I and HIV.

**Intestinal helminthiasis.** Intestinal helminth infection is ubiquitous in low-income tropical countries. Although such helminths do not appear to act as OIs in AIDS, it has been hypothesized that the immune dysregulation associated with geohelminthic infections may alter the natural history of HIV infection in an unfavorable manner. Such hypotheses are founded on the presence of chronic immune activation and Th2 polarization during chronic helminthic infection. Indeed, it has been demonstrated that peripheral blood cells from patients with intestinal helminth infection<sup>68</sup> (and filarial infection<sup>69</sup>) are more susceptible to in vitro infection with HIV than are cells from helminth-uninfected patients. The overall hypothesis remains unproven, however. An initial study from Ethiopia indicated that HIV viral load was significantly higher in individuals with various helminthic infections than in individuals without helminths, correlating positively with the parasite load as well as decreasing after elimination of the worms by antiparasitic treatment.<sup>70</sup> However, similar studies

performed in Uganda and examining far larger numbers of patients have convincingly failed to replicate these findings.<sup>71,72</sup> These latter studies strongly suggest that helminth coinfection is not associated with faster progression of HIV disease.

***Onchocerca volvulus.*** Among the filaria, the effect of HIV coinfection has been studied in a large cohort of patients with *Onchocerca volvulus* infection. No significant epidemiological association was found between the two infections, nor was there any difference in the efficacy of ivermectin treatment in HIV-infected compared with -uninfected patients.<sup>309</sup>

## Arthropods

*Sarcoptes scabiei* var. *hominis* stands alone among the arthropod and crustacean infestations of humans as a cause of exacerbated disease in the presence of HIV infection. In normal hosts, scabies is usually manifest as a markedly pruritic, papular, and vesicular dermatitis, with pathognomonic burrows harboring gravid females. Excoriations, nodules, and eczematous or impetiginized plaques may also be found. Relatively few adult mites are normally present.

Norwegian or crusted scabies is seen in neurologically impaired or immunosuppressed patients. Pruritus is often absent or mild. Lesions consist of widespread hyperkeratotic, crusted, scaling, fissured plaques. The nails are frequently involved. Patients tend to be heavily infested, with thousands of adult mites (see Chapter 118). Crusted scabies has been reported as a complication of HIV infection. CD4+ T-cell counts in reported cases have been less than 500/ $\mu$ L.<sup>310–312</sup> Both typical and atypical presentations are seen, the latter including the “pruritus of AIDS,” crusting with pruritus, pruritic papular dermatitis, and mimics of Darier’s disease and psoriasis.<sup>311</sup> Secondary sepsis and death have been reported.<sup>313</sup> In the face of this clinical variability, the diagnosis of crusted scabies in HIV-seropositive people rests on appropriate clinical suspicion and the demonstration of heavy infestation by microscopic examination of skin scrapings. With such extraordinary mite loads, these patients are remarkably contagious.<sup>314,315</sup> Combination therapy with ivermectin 200  $\mu$ g/kg and topical benzyl benzoate (or perhaps permethrin) appears to be the treatment of choice.<sup>312</sup> Single-dose ivermectin is also effective at preventing transmission in close contacts. Despite speculation early in the AIDS pandemic, there is no evidence of transmission of HIV by arthropod vectors.

Pruritic papular eruptions associated with HIV infection are common in sub-Saharan Africa. The etiology of these intensely pruritic lesions has been attributed to exaggerated immune responses to arthropod bites in HIV-infected individuals.<sup>316</sup>

## Fungal Infections

### *Penicillium marneffei*

Disseminated infection with *P. marneffei*, a dimorphic fungus endemic to Southeast Asia and southern China (see Chapter 82), has emerged as an important OI in AIDS patients. It is the third most common OI in HIV disease in northern Thailand, after extrapulmonary tuberculosis and cryptococcal meningitis.<sup>316</sup> First isolated in 1956, infection with *P. marneffei* was a rare event before the arrival of the AIDS

pandemic in Southeast Asia.<sup>316</sup> Since then, thousands of cases have been diagnosed, primarily in southern China, northern Thailand, Hong Kong, Taiwan, Malaysia, Vietnam, Singapore, Indonesia, and Myanmar.<sup>316–320</sup> The overwhelming majority of cases have been in AIDS patients, although normal hosts are also known to develop systemic disease with this fungus.<sup>316,318,321</sup> There is a pronounced intracountry variation in infection rates. In northern Thailand, up to one-fourth of AIDS patients suffer disease with it, whereas in southern Thailand the prevalence is 10-fold less.<sup>320</sup> The environmental reservoir for *P. marneffei* is unknown, but the organism has been isolated from the organs, feces, and burrows of three species of bamboo rats. The geographic range of these rodents overlaps the previously mentioned known areas of endemicity for disease with *P. marneffei*<sup>317–319</sup> and suggests the likelihood that this fungus is also endemic in Laos, Cambodia, and Malaysia.<sup>316</sup> Whether bamboo rats are important reservoirs for human infection or just another natural host is unclear. There is no evidence of transmission between rats and humans. The seasonal distribution of the diagnosis of disseminated disease in AIDS patients suggests that the reservoir for *P. marneffei* expands during the rainy season.<sup>317</sup> Exposure to soil appears to be a key factor.<sup>322</sup>

The pathogenesis of disease due to *P. marneffei* is presumed by analogy with other endemic systemic mycoses to involve transmission by inhalation, with secondary systemic dissemination. Like *Histoplasma capsulatum*, *P. marneffei* is an intracellular parasite of monocyte/macrophages.<sup>318</sup> A murine model of pulmonary and disseminated infection shows that T cells play a central role in controlling infection.<sup>323</sup> In AIDS patients, disseminated disease is associated with CD4+ T-cell counts less than 100/ $\mu$ L.<sup>316,324</sup>

The largest clinical series reported to date of AIDS patients with disseminated *P. marneffei* infection provided detailed information on 80 patients.<sup>316</sup> The onset of symptoms was generally sudden and intense. The most common presenting symptoms and signs were fever (92%), anemia (77%), weight loss (76%), and skin lesions (71%). Other frequent signs and symptoms included cough (49%), generalized lymphadenopathy (58%), hepatomegaly (51%), and diarrhea (31%). The most common cutaneous manifestation (87%) was a generalized papular rash with central umbilication that resembled the lesions of molluscum contagiosum. These were predominantly found on the face, scalp, and upper extremities but occurred throughout the body, including the palate. Other cutaneous lesions included papules without umbilication, a maculopapular rash, subcutaneous nodules, acne-like lesions, and folliculitis. Chest films were frequently abnormal, with diffuse reticulonodular or localized alveolar infiltrates the most common.

The mean duration of illness prior to presentation in this study was 4 weeks. The incubation period for disseminated disease is unclear, as is the percentage of patients whose disease is a result of reactivation of latent infection, as opposed to new infection or reinfection. The fact that reactivation with increasing immunosuppression occurs is supported by the several cases of disseminated disease reported from non-endemic areas in AIDS patients who had a distant history of travel to endemic areas.<sup>324,325</sup> Many such patients had spent little time in endemic areas, indicating that infection with *P. marneffei* can occur rapidly. The development of clinically active disease within weeks of exposure in endemic areas<sup>326</sup>

and the reports of children with vertically transmitted HIV infection developing disease in the first months and years of life<sup>327</sup> demonstrate that primary infection can quickly lead to disseminated disease. Finally, the pronounced seasonal variation in disease incidence implies an important role for exogenous reinfection in the expression of disease with *P. marneffei* in AIDS patients in endemic areas.<sup>317</sup>

The mortality rate of patients with disseminated *P. marneffei* infection is very high in the absence of prompt treatment. Diagnosis depends on a high index of suspicion, including a careful history to assess possible residence or travel in an endemic area. The differential diagnosis includes tuberculosis, other endemic fungi, and cryptococcosis. Cutaneous lesions may mimic those of AIDS-related molluscum contagiosum, *Histoplasma capsulatum* and *Cryptococcus neoformans*. An absence of cutaneous lesions may retard diagnosis. In this regard, a characteristic syndrome of hepatic disease in the absence of skin lesions (fever, hepatomegaly, and markedly elevated serum alkaline phosphatase levels) should be noted.<sup>328</sup> A presumptive diagnosis can be made by the examination of a Wright's-stained bone marrow aspirate, lymph node aspirate, or touch preparations of skin biopsy specimens.<sup>316,318,329</sup> Intracellular and extracellular basophilic elliptic yeast-like organisms with central septation (as opposed to the budding of *H. capsulatum*) are characteristic. Indirect fluorescent antibody reagents have been developed that may prove useful for differentiating *P. marneffei* from *H. capsulatum* and *C. neoformans* in tissue.<sup>330</sup> Characteristic intracellular organisms have been detected on routine blood smears.<sup>331</sup> In the previously discussed series, definitive diagnosis was performed by culture of *P. marneffei* from blood (76%, even in the absence of routine lysis-centrifugation culture), skin biopsy (90%), bone marrow (100%), and sputum (34%). Diagnostic antigenemia tests that may prove valuable for rapid diagnosis have been developed.<sup>332,333</sup> Quantitation of urinary antigen by enzyme immunoassay (employing rabbit hyperimmune IgG) is especially promising: High sensitivity and specificity were demonstrated in an area of high endemicity.<sup>334</sup> Of note, *P. marneffei* infection is a known cause of false-positive reactions in the *H. capsulatum* polysaccharide antigen immunoassay.<sup>335</sup> Current serologic assays are unlikely to be helpful in the diagnosis of AIDS patients but, with improved sensitivity, may provide a useful index of infection.<sup>330,336</sup>

Amphotericin B, 0.6 mg/kg/day for 2 weeks, followed by itraconazole, 200 mg twice a day for 10 weeks, is safe and effective.<sup>337</sup> In mild to moderately ill patients, primary therapy with itraconazole may be reasonable. Secondary prophylaxis is mandatory, given relapse rates of 50% within 6 months in its absence.<sup>338</sup> A placebo-controlled, double-blind randomized trial showed that secondary prophylaxis with itraconazole (200 mg once daily) is safe and effective.<sup>78,339</sup> With immune reconstitution as a result of a successful response to HAART, discontinuation of secondary prophylaxis is probably safe.<sup>340</sup> A controlled, double-blind trial of primary prophylaxis with itraconazole (200 mg once daily) in Thai patients with AIDS and CD4+ T-cell counts less than 200/ $\mu$ L showed that the regimen was well tolerated and effective at preventing both cryptococcosis and penicilliosis.<sup>341</sup> No survival benefit was found, but the study was not powered to detect a survival advantage.<sup>341</sup>

### *Paracoccidioides brasiliensis*

The dimorphic fungus *P. brasiliensis* is the cause of the most common systemic mycosis in Latin America (see Chapter 81). Two clinical forms are distinguished in normal hosts: an acute or subacute “juvenile” form and a chronic “adult” form. Acute, juvenile disease, occurring in children and young adults and accounting for a small minority of cases (3% to 5%), is marked by a rapid course, disseminated involvement of monocyte/macrophages and lymphoid tissue, and severe suppression of CMI. Chronic, adult disease, accounting for the vast majority of cases, is a slowly progressive disease, predominantly of older men. In most patients, the primary clinical and pathologic manifestations are pulmonary, with nodular, infiltrative, or cavitary lesions progressing to fibrosis. Other frequent manifestations of adult disease include infiltrative and ulcerative mucosal lesions of the oro- and nasopharynx, polymorphic cutaneous lesions, lymphadenopathy, and adrenal infiltration. Most infections are subclinical. Long latency has clearly been demonstrated, with a mean of 15 years between leaving an endemic area and presentation.<sup>342</sup>

It is thought that CMI responses are critical to the host defense from disease with *P. brasiliensis*.<sup>342,343</sup> Clinical and experimental evidence indicates that paracoccidioidomycosis is associated with marked abnormalities of immune function, with suppression of CMI responses, polyclonal B-cell activation, and elevation of plasma IgE levels.<sup>342–344</sup> These immunologic perturbations are more common and severe in juvenile disease and are reversed with successful therapy.<sup>342</sup>

Given the immunology of paracoccidioidomycosis, one might expect it to be a prominent OI in South America and among HIV patients with a history of travel there. In fact, fewer than 100 cases have been reported, despite the presumed wide prevalence of infection or coinfection in areas such as urban Brazil.<sup>345–348</sup> Possible reasons for the low number of cases in HIV-seropositive patients include (1) prophylaxis with TMP-SMX, which has activity against *P. brasiliensis*; (2) the use of ketoconazole for oropharyngeal candidiasis; (3) misdiagnosis as PCP, with a therapeutic response to TMP-SMX; (4) lack of diagnosis; and (5) the presence of a particularly subtle interaction between HIV and *P. brasiliensis*.<sup>345,348</sup>

Paracoccidioidomycosis in HIV-seropositive people has been primarily of the “acute” form, with prominent involvement of the reticuloendothelial system. However, pulmonary and oral mucosal involvement, more typical of the “chronic” form, often coexists.<sup>346</sup> Although published reports have suggested that this disseminated disease may occur across a broad range of HIV-associated immunosuppression, CD4+ T-cell counts less than 200/μL have been the reported norm.<sup>346,347</sup> More than one-third of patients with paracoccidioidomycosis have presented with another opportunistic coinfection, most frequently oral/esophageal candidiasis or tuberculosis.<sup>346</sup> Reported clinical presentations span a wide spectrum, from relatively indolent to rapidly progressive disease. Clinical manifestations have included prolonged fever, weight loss, cough, dyspnea, generalized lymphadenopathy, hepatosplenomegaly, skin lesions (localized or disseminated maculopapular, nodular, or ulcerative), oral lesions (ulcerative and/or nodular), osteoarticular lesions, and meningitis.<sup>345,346</sup>

Diagnosis in these patients was made by direct examination or culture of clinical specimens, including skin biopsies,

lymph node aspirates or biopsies, bone marrow aspirates, CSF, or blood.<sup>345,346</sup> Sputum should also be examined using potassium hydroxide preparations, calcofluor stains, or immunofluorescence. The “pilot wheel” cell, consisting of numerous small buds surrounding the mother cell, is characteristic. Serologies have not been diagnostically helpful.

Mortality in the reported cases of disease in HIV-seropositive people was 30%.<sup>345</sup> No randomized clinical trials have been performed with any of the drugs commonly used for the treatment of *P. brasiliensis* infection (sulfonamides, amphotericin B, ketoconazole, and itraconazole), even in normal hosts. Treatment recommendations are based on data from case series and comparison with historical controls.<sup>348</sup> However, the data are fairly compelling that itraconazole (100 mg/day) is the drug of choice in normal hosts.<sup>342</sup> Published reports of itraconazole treatment in the face of HIV coinfection are scant.<sup>346,347</sup> Although amphotericin B and itraconazole may both have therapeutic roles to play, amphotericin B should probably be used for initial treatment in HIV coinfecting patients. Lifelong suppressive therapy is necessary; itraconazole seems to be a reasonable choice.

### *Histoplasma capsulatum* var. *duboisii*

The endemic dimorphic fungus *H. capsulatum* var. *duboisii* is localized to western and central Africa and Madagascar (see Chapter 88). In normal hosts, it tends to cause chronic necrotizing cutaneous and skeletal infections. Disseminated disease is unusual. It may be an emerging OI in AIDS patients. No increases in the incidence of African histoplasmosis were reported in a study from the People's Republic of the Congo (now Congo Republic) in the 1980s, despite a rapid increase in the AIDS-related incidence of cryptococcal disease.<sup>349</sup> Disease manifestations reported in the handful of HIV-*H. capsulatum* var. *duboisii* coinfections described in the literature, however, suggest that AIDS patients are at risk of more severe, disseminated disease.<sup>350–355</sup> Diagnosis is by direct examination of clinical specimens and culture. The yeast form is larger and has a thicker wall than *H. capsulatum* var. *capsulatum*. Amphotericin B and itraconazole have therapeutic efficacy.

### *Sporothrix schenckii*

The dimorphic fungus *S. schenckii* has a worldwide distribution, although most reports have been from tropical and subtropical areas of the Americas (see Chapter 84). The highest incidence of disease is thought to be in the highlands of Mexico and in southern Brazil. Cutaneous and lymphocutaneous disease is most common. Extracutaneous involvement, including osteoarticular disease, pneumonia, and meningitis, has been described in both normal and immunosuppressed hosts. A handful of cases of severe, disseminated sporotrichosis in late-stage AIDS have been described.<sup>356–358</sup> Diffuse cutaneous involvement is the norm. Some patients have also presented with CNS, ocular, osteoarticular, splenic, bone marrow, and/or mucosal involvement. It appears likely that disseminated *Sporothrix* will become a more prominent OI in heavily endemic areas. The response to therapy (with amphotericin B, potassium iodide, itraconazole, ketoconazole, and 5-fluorocytosine) has been variable and problematic. Amphotericin B should probably

be used for initial treatment, followed by lifelong suppressive therapy with itraconazole.<sup>359</sup>

### Other Endemic, Systemic Mycoses

*Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis* are systemic mycoses endemic to the United States that cause OIs in AIDS patients. As such, they are obviously not distinctly tropical diseases and have been covered in-depth elsewhere.<sup>76–79,360–362</sup> The tropical extent of their respective areas of endemicity deserves brief mention, however.

*Histoplasma capsulatum* var. *capsulatum* (see Chapter 80) is found in distinct river basin systems worldwide between 45° N and 30° S of the equator.<sup>360</sup> Progressive disseminated histoplasmosis is common in AIDS patients in endemic areas.<sup>360</sup> In addition to the most prominent worldwide focus (the Ohio and Mississippi River valleys of the United States), cases have been reported from Central and South America, the Caribbean, Africa, Southeast Asia, and Europe.<sup>363,364</sup>

Disease caused by *B. dermatitidis* was originally named North American blastomycosis. It is now clear, however, that the distribution of this fungus is far more cosmopolitan (see Chapter 80). Blastomycosis has been reported in all the major regions of Africa, with a concentration in southern Africa. It is likely underreported.<sup>365</sup> Occasional cases have been reported from Central and South America, the Middle East, and India.<sup>366</sup> African strains of *B. dermatitidis* appear to be antigenically distinct from North American strains. The clinical spectrum likewise appears to be different in African cases, with prominent involvement of bone and chronic draining sinuses. Disseminated blastomycosis is an uncommon, late, frequently fatal OI in patients with AIDS in the United States.<sup>367,368</sup> Cases in Africa are to be expected in the future.

*Coccidioides immitis* is endemic to lower Sonoran life zones in the United States, Mexico, Guatemala, Honduras, Colombia, Venezuela, Bolivia, Paraguay, and Argentina (see Chapter 80). Coccidioidomycosis is a severe, often fatal disease in patients with AIDS and low CD4+ T-cell counts.<sup>362,369,370</sup> Most have presented with diffuse or focal pulmonary disease; extrapulmonary dissemination is not uncommon. In some endemic areas, it is the third most common OI in AIDS patients.<sup>362,369,370</sup>

### *Cryptococcus neoformans*

Cryptococcosis (see Chapter 80) is a common life-threatening fungal infection in AIDS patients.<sup>371</sup> Although the dissemination of *C. neoformans* can affect almost any organ system in HIV-infected people, meningitis is the most frequent manifestation. Other relatively common manifestations include pneumonia and cutaneous lesions. Occurring most commonly when CD4 counts fall well below 200/μL, cryptococcosis is a frequent presenting diagnosis in AIDS.<sup>371</sup> Excellent reviews on cryptococcosis in AIDS are available for detailed information on the clinical approach to this ubiquitous OI.<sup>76–79,372</sup>

*Cryptococcus neoformans* is distributed globally. The distribution of cryptococcus as an OI in AIDS is global as well. Regional differences exist in the prevalence of disease as

defined by clinical or autopsy series. The prevalence of cryptococcosis in AIDS patients in the United States was estimated to be 7% or 8% in the 1980s.<sup>373</sup> In Thailand, it is the second most common OI (after tuberculosis), with a prevalence of 13% to 44% in different clinical series.<sup>21,374,375</sup> In Africa, the case series prevalence has been variable, from 1% in Soweto, South Africa,<sup>376</sup> to 6% to 13% in Kinshasa (the former Zaire).<sup>377–379</sup> The prevalence in autopsy series has similarly varied from 3% in Abidjan (Côte d'Ivoire)<sup>209</sup> to 29% in Uganda.<sup>211</sup> Overall, the rates of disease in Africa appear to be higher than those in North America or Europe. Interestingly, a large retrospective case study in London found a significantly higher rate of extrapulmonary cryptococcal disease in Africans attending an HIV clinic than in non-Africans attending the same clinic.<sup>380</sup> Data from case series estimated the prevalence of cryptococcosis in Mexico to be 8% to 12%<sup>381</sup> and in Haiti 13%.<sup>382</sup> In Brazil, from 1980 to 2002, 6% of patients had cryptococcus as an AIDS-defining diagnosis.<sup>383</sup>

*Cryptococcus neoformans* exists in two varieties: *C. neoformans* var. *neoformans* and *C. neoformans* var. *gatti*. They inhabit different ecological niches, with *C. neoformans* var. *neoformans* being associated with soil contaminated with bird excrement and *C. neoformans* var. *gatti* having a unique, if poorly understood, association with the tree *Eucalyptus camaldulensis*.<sup>384,385</sup> Whereas *C. neoformans* var. *gatti* has a predominantly tropical and subtropical distribution, *C. neoformans* var. *neoformans* occurs worldwide.<sup>384,385</sup> Of note, although cryptococcosis due to *C. neoformans* var. *gatti* occurs with some regularity in normal hosts in regions where this variety is endemic, cases of cryptococcosis in AIDS patients have been almost exclusively due to *C. neoformans* var. *neoformans*.<sup>385,386</sup>

### *Pneumocystis jiroveci* (Previously *P. carinii* f. spp. *hominis*)

Throughout the world, there is almost universal serologic evidence of exposure by the age of 2 years to *P. jiroveci*, a ubiquitous fungus<sup>387</sup> (see Chapter 85). The prevalence of antibodies to specific *P. jiroveci* antigens varies, however, suggesting exposure to antigenically different strains in different areas of the world,<sup>388</sup> which is mirrored by genetic studies revealing strain differences in this organism.<sup>389</sup> PCP (*Pneumocystis carinii* pneumonia, based on the prior terminology) remains the most frequent serious OI in the United States and Europe, despite dramatic decreases in incidence due to the introduction of HAART.<sup>390,391</sup> Prior to HAART, it occurred in 40% to 50% of patients with a CD4 count less than 100/μL per year, and in 60% to 80% of patients overall, in the absence of prophylaxis.

HAART is far from widely available in much of the tropics, and PCP prevalence appears to be high, as expected, among AIDS patients in Central and South America and in Asia.<sup>391</sup> Interestingly, however, the incidence of PCP in adult AIDS patients in Africa is thought to be far lower than was seen in the pre-HAART era in industrialized countries.<sup>391</sup> Adult clinical series in Africa have shown prevalence rates of 0% to 22%.<sup>376,382,392–395</sup> Studies including bronchoscopy for diagnosis have described rates of 0% to 39% (the highest figures being obtained as a percentage of acid-fast bacillus-negative pneumonias).<sup>382,392,396–398</sup> Autopsy series have had rates of 0% to 11%.<sup>210,394,399</sup>

The reasons for these lower rates of PCP in Africa are unclear. Possible explanations include less environmental exposure to *P. jiroveci*, exposure to differing strains of *P. jiroveci*, differences in host susceptibility, earlier deaths in tropical patients with AIDS due to exposure to more virulent organisms, diagnostic difficulties, and host-specific differences in susceptibility.<sup>382,400</sup> Exposure to *P. jiroveci* appears to be similar worldwide.<sup>387,388</sup> As noted previously, the existence of genetically and antigenically distinct human strains is likely; however, pediatric PCP rates in AIDS patients in Africa are quite similar to those in the industrial north.<sup>391,401</sup> Indeed, approximately one-third of HIV-infected infants in Africa die during the first year of life, and PCP is thought to be responsible for 30% to 50% of such deaths.<sup>402,403</sup> Demise from more virulent pathogens prior to clinical PCP may well occur in adults (and PCP does tend to occur early in the course of HIV disease in North American infants,<sup>404</sup> perhaps with initial exposure<sup>79</sup>). The high prevalence of cryptococcal disease in these same series, which is thought to occur at similar levels of immunosuppression, suggests that this is not the complete answer.<sup>382</sup> Diagnostic difficulties may also play a role, but these have been well addressed in several of the cited studies.

The clinical presentation of PCP in the tropics appears to be similar to that in the industrial north.<sup>398</sup> Frequent coinfection with tuberculosis may obscure the diagnosis. Multiple reviews of the clinical approach to PCP in AIDS are available.<sup>76–79,405</sup>

### Other Fungi

Other predominantly tropical fungi, such as the agents of maduromycosis, lobomycosis, rhinosporidiosis, and subcutaneous zygomycosis, may prove to cause opportunistic infection in AIDS patients but have not been reported as such. Isolated case reports of infection due to a variety of unusual fungi in AIDS patients have been published (reviewed in Kaplan and colleagues,<sup>20</sup> Vartivarian and associates,<sup>406</sup> and Perfect and Schell<sup>407</sup>). Some may indeed prove to be OIs, even predominantly tropical OIs, but firm data are lacking. The common occurrence of superficial and invasive infections with *Candida* and the growing problem of *Aspergillus* infection in neutropenic long-term survivors of late-stage AIDS are beyond the scope of this chapter.

### Mycobacterial Infections

#### *Mycobacterium tuberculosis*

Although tuberculosis (see Chapter 36) is not usually perceived as a tropical disease, the prevalence and mortality of the disease in the tropics far surpass those in the industrial countries of the temperate zones. Approximately one-third of the 39.4 million people living with HIV worldwide are coinfecting with *M. tuberculosis*, 70% of whom live in sub-Saharan Africa.<sup>2</sup> In developing countries, 50% of patients with HIV infection will develop active tuberculosis; in contrast, in the United States, only 4% of patients with AIDS have had tuberculosis.<sup>2,408</sup> In some countries in sub-Saharan Africa, more than 70% of tuberculosis patients are HIV-seropositive. Tuberculosis is the leading cause of death among people with HIV infection, accounting for one-third of AIDS deaths worldwide.<sup>409</sup> The introduction of HAART has decreased death and OIs such as tuberculosis by

60% to 90% among people living with HIV worldwide in affluent countries<sup>410</sup>; in developing countries, however, HAART remains available only to a small minority of those who need it.

Tuberculosis was one of the earliest OIs to be linked to HIV infection and in many developing countries is the most common serious OI associated with HIV.<sup>408</sup> Tuberculosis is a relatively early complication of HIV, occurring before other AIDS-defining illnesses in 50% to 67% of HIV-infected patients.<sup>411</sup> Several relevant CMI functions, including lymphocyte proliferation and cytolytic T-cell activity, have been shown to be significantly suppressed in HIV-infected patients with tuberculosis. Additional host responses that may be impaired include the elaboration of cytokines such as IFN- $\gamma$  and IL-2. CD4+ T-cell counts are suppressed in tuberculosis patients, both with and without HIV coinfection, and rise with therapy for tuberculosis.<sup>412</sup>

Although the consequences of coinfection appear to adversely affect the tuberculous process mainly, there is also evidence, albeit somewhat controversial, of a deleterious effect of tuberculosis on the course of HIV disease. Several studies have shown that in vitro HIV replication is enhanced in blood monocytes from patients with active pulmonary tuberculosis and in lymph node mononuclear cells and CD4+ T cells from HIV-infected, purified protein derivative (PPD) skin test–positive patients after stimulation with PPD.<sup>413</sup> On the other hand, both enhancement and suppression<sup>55</sup> of HIV replication in monocytes have been reported after in vitro infection with *M. tuberculosis*. In vivo, plasma viral load has been shown to be higher in HIV-infected patients with active tuberculosis than in HIV-infected people without active tuberculosis, remaining high throughout the course of treatment.<sup>413–417</sup> However, whether tuberculosis increases HIV load, or whether higher HIV load is really a marker of increased risk for tuberculosis in coinfecting patients, remains unclear.<sup>47</sup> Similarly, although tuberculosis has been associated with reduced survival in HIV-infected patients,<sup>46,418–420</sup> direct and indirect lines of evidence have suggested the relation may well not be a directly causal one.<sup>28,421,422</sup>

The prophylaxis, diagnosis, and treatment of tuberculosis in the presence of HIV coinfection have been dealt with in depth elsewhere.<sup>76–79</sup> Certain issues of particular relevance to the tropics are explored further here.

Primary preventive therapy against tuberculosis with isoniazid has been shown to be effective in HIV-infected individuals, regardless of tuberculin status.<sup>423,424</sup> Meta-analyses have suggested a reduction in tuberculosis incidence of 60% to 68% in those with a positive tuberculin test and a reduction of approximately 42% among all treated individuals.<sup>423,424</sup> WHO/UNAIDS recommendations are for primary preventive therapy to be given to PPD-positive, HIV-infected individuals who do not have active tuberculosis.<sup>425</sup> In settings where it may not be feasible to do PPD testing, WHO/UNAIDS recommendations are for primary preventive therapy to be considered for those living in populations with a prevalence of tuberculous infection estimated to be more than 30%, health-care workers, household contacts of tuberculosis patients, prisoners, miners, and other groups at high risk of acquisition or transmission of tuberculosis. Although studies have shown that “short-course” therapy with rifampin plus pyrazinamide for 2 months is as efficacious as 6 to 12 months of isoniazid in preventing active tuberculosis in HIV-infected adults with positive tuberculin skin tests,<sup>426–428</sup> the side effects

associated with this regimen (in the general population and not, apparently, in the HIV-infected population) have left isoniazid the prophylactic agent of choice.<sup>429,430</sup>

Treatment of active, susceptible tuberculosis with first-line drugs is as effective for curing tuberculosis in HIV-infected as in HIV-uninfected individuals. In the absence of HAART, however, the death rate for those under treatment for tuberculosis is higher for people with HIV infection alone, mainly due to other OIs. Conflicting reports on increased rates of tuberculosis recurrence in the face of HIV coinfection<sup>431</sup> have not provided sufficient evidence for increasing the duration of treatment. Combining HAART with tuberculosis treatment is difficult for several reasons: overlapping toxicity profiles of some antituberculosis and antiretroviral drugs, drug interactions, and nonadherence with complicated treatment regimens.<sup>432</sup> An important problem is the possibility of paradoxical reactions. Such reactions include the transient worsening or appearance of new signs, symptoms, or radiographic manifestations of tuberculosis within days to weeks after initiating antiretroviral treatment. These reactions, likely due to immune reconstitution, may be particularly severe when HAART is started soon after initiating treatment for active tuberculosis. The Centers for Disease Control and Prevention (CDC)/ American Thoracic Society recommendations for tuberculosis treatment are to (1) continue previously started HAART; (2) avoid initiating HAART and tuberculosis therapy at the same time; and (3) always start tuberculosis therapy first, delaying HAART initiation until the first 1 or 2 months of tuberculosis therapy have been completed.<sup>432</sup>

Many of the world's children are vaccinated with bacille Calmette-Guérin (BCG). The risk:benefit ratio of vaccination is surely altered by the presence of HIV infection. On the risk side, there are a few case reports of localized or disseminated disease due to BCG in children and adults.<sup>433-436</sup> Disseminated disease in most hosts is a devastating event, with an overall mortality of 70%, and usually occurs in the immunosuppressed patient. Whether local or disseminated disease was due to HIV coinfection in the cited cases remains unclear, however.<sup>433-439</sup> On the side of potential benefit, the efficacy of BCG in HIV-infected populations is unclear. Data supporting both a lack of benefit of vaccination in HIV-seropositive children and a benefit of childhood vaccination in HIV-seropositive adults in protection from disease due to *M. tuberculosis* have been published.<sup>440,441</sup> Any such benefit would likely be multiplied by the much higher risk of tuberculosis in the face of concurrent HIV infection. Furthermore, data suggesting a beneficial effect of early BCG vaccination on mortality from all causes in HIV-uninfected children suggest that measures of benefit in HIV-seropositive patients need to be broader than mere prevention of tuberculosis.<sup>442</sup>

BCG vaccination remains in the WHO Expanded Programme on Immunization (EPI).<sup>443</sup> WHO recommendations are that BCG be given to children with asymptomatic HIV infection in areas with a high risk of tuberculosis infection. BCG is not recommended for those with symptomatic HIV infection (defined as AIDS). In areas where the risk of tuberculosis is minimal, BCG is not recommended for people known or suspected of being infected with HIV.<sup>443</sup> The use of BCG in HIV-seropositive patients is considered to be contraindicated under U.S. Public Health Service-Infectious Disease Society of America (USPHS-IDSA) guidelines<sup>213</sup> and by the Advisory Committee on Immunization Practices (ACIP).<sup>444</sup>

### ***Mycobacterium avium***

The *M. avium* complex (MAC) (see Chapter 36) consists of 28 serovars of two *Mycobacterium* species, *Mycobacterium avium* and *Mycobacterium intracellulare*. MAC bacteria are ubiquitous, with organisms commonly being isolated from soils, natural sources of water, tap water, and domestic and wild animals worldwide.<sup>445,446</sup> Most MAC isolates from AIDS patients are *M. avium*; more than 90% are of serovars 1, 4, and 8.<sup>447,448</sup> Disseminated disease due to *M. avium* is the most common systemic bacterial infection in AIDS patients in the industrial north, occurring in up to 43% of AIDS patients in the United States.<sup>449,450</sup> Disease occurs almost exclusively in those with CD4+ T-cell counts less than 100/ $\mu$ L, most frequently in those with CD4+ T-cell counts less than 50/ $\mu$ L.<sup>450</sup> The pathogenesis of disseminated *M. avium* infection in AIDS is thought to involve primary infection (or reinfection) as opposed to reactivation, with initial colonization of the respiratory or gastrointestinal tracts followed by widespread dissemination.<sup>451-453</sup> Systemic disease is marked by high-grade mycobacteremia (almost exclusively in monocytes) and impressive tissue burdens of bacteria.<sup>454</sup>

The remarkable feature of *M. avium* in the tropics is the apparent virtual absence of disseminated disease in AIDS patients in many areas, predominantly in sub-Saharan Africa. None of 95 blood cultures from severely ill patients with advanced AIDS in Uganda were positive for *M. avium*, nor were any of 165 mycobacterial sputum cultures from HIV-seropositive and -seronegative patients at the same hospital found to be positive for *M. avium*.<sup>455,456</sup> None of 202 blood cultures from HIV-positive adult inpatients in Côte d'Ivoire grew *M. avium* (whereas 4% grew *M. tuberculosis*).<sup>457</sup> None of more than 200 diagnostic lymph node biopsies in HIV-seropositive African patients had histology characteristic of disseminated *M. avium* infection.<sup>211</sup> Intestinal biopsies from 98 Ugandan, Zairian, and Zambian patients with chronic HIV-related enteropathy yielded histology suggestive of *M. avium* infection in only 1 patient.<sup>304,458,459</sup> Autopsies on 78 HIV-seropositive children in Côte d'Ivoire revealed no evidence of *M. avium* infection, whereas autopsies on 247 adult HIV patients in Côte d'Ivoire revealed a 3% prevalence of pathologic changes "indicative of atypical mycobacteriosis."<sup>209</sup> In contrast, 3 of 48 (6%) patients hospitalized in Kenya with late-stage HIV disease had *M. avium* bacteremia.<sup>460</sup> Clinical and autopsy series from Mexico have revealed a prevalence of disseminated disease due to *M. avium* of 4% to 6%,<sup>210,461</sup> whereas 18% of 125 hospitalized patients with AIDS in Brazil had *M. avium* cultured from bone marrow.<sup>462</sup> Few data are available from India and Southeast Asia.

The reasons for the apparent absence of disseminated disease due to *M. avium* in areas of the tropics are unclear. As with the decreased prevalence of PCP, many explanations have been proposed, including less exposure to *M. avium*, exposure to different (less pathogenic) variants of *M. avium*, differences in host susceptibility, greater acquired immunity to mycobacteria, earlier death by more virulent pathogens, and diagnostic difficulties. Overall exposure to MAC organisms is likely to be similar. Environmental isolation of MAC occurs with similar or greater frequency in Congo and Uganda than in the United States,<sup>446,456</sup> and skin test surveys suggest a similar frequency of exposure to MAC in economically developed and developing countries.<sup>463</sup> Piped water systems in the

United States and Europe have a higher frequency of MAC isolation, however, and economic conditions may lead to greater exposure to MAC-containing droplets via showerheads in economically developed countries<sup>445,446,464</sup>; such differences, however, are unlikely to lead to an essentially total absence of disease in countries such as Uganda. Exposure to different *M. avium* serovars or strains may well be important. Data on serotyping of African clinical strains are scarce. Preliminary data suggest that African clinical isolates are distinguishable from European and American isolates by restriction fragment length polymorphism analysis.<sup>465</sup> The possibility of underlying genetic differences in host susceptibility is belied by the similar rates of disseminated *M. avium* infection as a presenting diagnosis in African and non-African AIDS patients in a London clinic.<sup>380</sup> Greater acquired immunity to mycobacterial disease through BCG vaccination<sup>441</sup> or prior infection with *M. tuberculosis* may exist, but the reported BCG coverage (50%) and PPD reactivity (82%) in Uganda seem unlikely to explain the lack of any disseminated MAC disease.<sup>456</sup> Earlier death due to a greater environmental presence of, or greater latent infection with, more virulent pathogens may occur. This is unlikely to be the entire explanation because patients in many of the previously mentioned studies had clinical late-stage AIDS. Finally, the design of several of the previous studies makes the assertion that the central problem is one of a lack of diagnostic sophistication untenable. Further data are awaited.

### *Mycobacterium leprae*

*Mycobacterium leprae*, the causative agent of leprosy (see Chapter 38), is an incredibly slow-growing parasite of monocyte/macrophages. For comparative purposes, it may be useful to recall that *Leishmania*, which infects similar cells, is a prominent opportunistic pathogen for patients with HIV infection. The importance of CMI in leprosy and leishmaniasis was emphasized by Turk and Bryceson<sup>466</sup> in their detailed comparison of skin lesions and histopathology of both diseases. Moreover, the immunopathology of both infections is very similar. In view of the widespread prevalence of leprosy in the tropics and subtropics, the immunosuppressive effects of HIV or AIDS on leprosy would be expected to become readily apparent, but there is little or no evidence of this interaction. In fact, in a comprehensive analysis of the possible interaction between HIV/AIDS and leprosy, Lucas concluded that leprosy appears to be another “missing infection in AIDS.”<sup>15</sup>

There is no quantitative measure of immune unresponsiveness in leprosy, such as the CD4 count in AIDS, as an indicator of clinical progression; however, there is general agreement that the tuberculoid form of disease is characterized by a well-organized granuloma on biopsy of a skin lesion or the lepromin reaction, with very few or no organisms (paucibacillary). Patients with lepromatous leprosy have a negative lepromin skin test, and biopsies of their skin lesions lack a granulomatous response and show large numbers of organisms (multibacillary). Some of the ways in which the adverse effects of HIV infection on leprosy could be manifested include an increase in the disease:infection ratio, a shift toward multibacillary disease, or an altered response to anti-leprosy chemotherapy. Of course, the presence of leprosy may also enhance HIV infection.

Several studies have examined positive serology for HIV in newly diagnosed leprosy cases. One report from a rural hospital in Zambia found a higher prevalence of reactors compared with blood donors and surgical patients (6 of 18 vs. 9 of 105), but the numbers were small and the controls were not adequately matched.<sup>467</sup> A larger study of HIV seroprevalence in northwest Tanzania of 93 new leprosy cases compared with more than 4000 controls found that the presence of HIV antibody was significantly associated with multibacillary disease.<sup>468</sup> The fact that this association was based on only five HIV-positive cases with multibacillary disease illustrates the complexity of epidemiologic analysis in a disease such as leprosy. Another comparison of seropositivity for HIV was carried out among 189 new cases of leprosy matched for age, sex, and district of residence with 481 controls in Uganda. No significant difference in overall positive rates was found (12% in cases vs. 18% in controls), but again, positive HIV reactions were more frequent among multibacillary cases.<sup>469</sup> A different clinical association was noted in Zambia in leprosy patients with active neuritis, which suggested that HIV-positive cases had poorer recovery of nerve function than controls after treatment with steroids.<sup>470</sup>

A factor that should be considered in evaluating reports of HIV/AIDS in leprosy patients is the greater likelihood of false-positive serologic reactions. One or more positive bands to HIV antigens in Western blots were commonly found in several hundred sera from northern India in the absence of positive enzyme-linked immunosorbent assays (ELISAs).<sup>471</sup> Another report claimed that 3 of 75 (4%) sera from Indonesia and 6 of 100 (6%) sera from Somalia gave positive HIV ELISAs but negative Western blots.<sup>472</sup> These were attributed to leprosy.

There appears to be no striking evidence that HIV infection has an adverse effect on the course of leprosy. There is a suggestion from several of the reports cited previously that multibacillary disease may develop under the influence of HIV infection; however, there are several features of leprosy that may tend to obscure an interaction with HIV infection. Both infections are chronic and slow in their progression, so it may simply take more time to recognize an influence of one on the other. Leprosy is predominantly a rural infection involving people not yet caught up with the ravages of HIV and AIDS. Patients with AIDS in the tropics may not survive long enough to display interactions with leprosy. Finally, patients in the early stages of leprosy have relatively subtle clinical manifestations with which physicians in the urban environment may not be familiar. Therefore, there may be more going on out there than we realize. It has been noted that HAART-associated immune reconstitution may trigger injurious inflammatory reactions in treated patients coinfecting with leprosy.<sup>473–475</sup>

### Other Nontuberculous Mycobacteria

Disease due to *Mycobacterium genavense* (see Chapter 36) mimics that due to *M. avium*, causing disseminated disease in AIDS patients with very low CD4+ T-cell counts (mean, <50/ $\mu$ L). The pathogenesis appears to involve initial gastrointestinal colonization followed by dissemination.<sup>476,477</sup> The important environmental reservoirs are unclear, but pet birds can have extensive gastrointestinal tract involvement.

The organism may also be present in tap water.<sup>478</sup> The geographic range of disease is only beginning to be defined. Cases have been reported from North America, Europe, and Australia.<sup>476</sup> The most common presenting symptoms and signs are fever, weight loss, abdominal pain, chronic diarrhea, lymphadenopathy, hepatosplenomegaly, “pseudo-Whipple’s disease,” and anemia.<sup>476,479,480</sup> Imaging of the spleen may suggest splenic abscesses<sup>481</sup>; diffuse nodular infiltrates may be seen in the lung.<sup>482</sup> Pathologically, involved organs are filled with histiocytes that are packed with acid-fast bacilli. The diagnosis can be established by the isolation of *M. genavense* from normally sterile sites (blood, bone marrow, lymph node, and spleen). Specific diagnosis is confounded by the fastidious growth requirements of the organism. Primary isolation on solid media is difficult, and growth in liquid broth may have only 50% sensitivity. Definitive identification demands PCR techniques.<sup>476</sup> The clear implication is that a significant percentage of cases ascribed to disseminated *M. avium* are likely due to *M. genavense*.<sup>479</sup> Data on treatment are all retrospective, but therapy appears to be associated both with improvement in symptoms and with survival. Multidrug regimens that include clarithromycin appear to be associated with the best clinical responses.<sup>483,484</sup>

Before the AIDS pandemic, *Mycobacterium kansasii* was known primarily as a cause of chronic pulmonary disease, resembling tuberculosis in lungs with underlying damage. *Mycobacterium kansasii* is second to MAC among nontuberculous mycobacteria as a cause of disease in HIV-infected patients in the United States.<sup>485</sup> Although *M. kansasii* has been reported as a cause of pulmonary disease in most areas of the world, most case reports of HIV coinfection are from North America and Europe. However, coinfection may be especially prevalent in the gold mines of the Transvaal in South Africa.<sup>486</sup> In HIV-infected individuals, disease due to *M. kansasii* and *M. tuberculosis* has very similar clinical and radiological characteristics.<sup>487</sup> A major difference (with epidemiological and prognostic implications) is that *M. kansasii* disease tends to occur later in the course of HIV infection. The mean CD4+ T-cell count at the time of presentation is approximately 50 to 60/ $\mu$ L<sup>487–489</sup>; 60% to 90% present with pulmonary disease alone and 20% to 35% with disseminated disease.<sup>489,490</sup> The incidence in industrialized countries has plummeted in the HAART era.<sup>491</sup> With all nontuberculous mycobacteria, differentiation between colonization, contamination, and disease can be problematic. Mere colonization of the respiratory tract with *M. kansasii* appears to be infrequent in AIDS patients, however. All pulmonary isolates should be taken seriously.<sup>488,490</sup> Despite relative in vitro resistance to isoniazid,<sup>491</sup> the recommended therapy is isoniazid, rifampin, and ethambutol. Therapy clearly alters survival in patients with pulmonary disease.<sup>489,490,492</sup> Disseminated disease has a particularly poor prognosis.

First described in 1977, *Mycobacterium malmoense* is an uncommon cause of pulmonary disease resembling tuberculosis. The environmental reservoir is unknown. Person-to-person transmission has never been documented. Multisystem disease with bacteremia has rarely occurred in the presence of profound immunosuppression, including several patients with AIDS and low CD4+ T-cell counts. Pulmonary and gastrointestinal disease, along with bacteremia, is usual.<sup>493,494</sup> In vitro susceptibility testing does not correlate well with clinical response.<sup>495</sup> The best regimen for pulmonary

disease in the nonimmunosuppressed patient appears to be isoniazid, rifampin, and ethambutol.<sup>495</sup> Optimal therapy in AIDS patients is unclear.

*Mycobacterium haemophilum* causes localized lymphadenitis in immunologically healthy children and cutaneous, osteo-articular, and, more rarely, pulmonary or disseminated disease in immunocompromised patients. Several cases have been reported in AIDS patients.<sup>496–500</sup> Cutaneous lesions include furuncles, abscesses, papules, vesicles, and deep ulcers. Such lesions are usually diffuse, most often on the extremities. Culture (at 30° to 32°C) demands supplementation of media with an iron source. In vitro susceptibility data and scattered clinical reports suggest that rifampin plus ciprofloxacin is reasonable empirical therapy. Other agents with good activity include amikacin, ciprofloxacin, and clarithromycin.<sup>498</sup> The environmental source and mode of infection are unclear.

Several other mycobacteria have been demonstrated or suspected to cause opportunistic disease in AIDS patients, including *Mycobacterium fortuitum* (primary pulmonary disease,<sup>501</sup> disseminated disease,<sup>502</sup> cervical lymphadenitis,<sup>502</sup> and meningitis<sup>503</sup>), *Mycobacterium marinum* (disseminated cutaneous and systemically disseminated disease<sup>504,505</sup>), *Mycobacterium celatum* (pulmonary and disseminated disease<sup>506,507</sup>), *Mycobacterium xenopi* (disseminated disease, pulmonary disease, and pulmonary colonization<sup>508–510</sup>), *Mycobacterium gordonae* (pulmonary, cutaneous, and disseminated disease<sup>511–513</sup>), *Mycobacterium scrofulaceum* (disseminated disease<sup>514</sup>), *Mycobacterium bovis* (disseminated disease), and *Mycobacterium simiae* (disseminated disease<sup>515,516</sup>). Although a smattering of case reports have suggested that HIV does not exacerbate disease due to *M. ulcerans*, the causative agent of Buruli ulcer,<sup>517</sup> a case report has called this into question.<sup>518</sup>

## Spirochetal Infections

Along with other genital inflammatory or ulcerative diseases, syphilis (see Chapter 44) has been implicated as a cofactor in HIV transmission. Many case reports have suggested that HIV infection can alter the course of disease with *Treponema pallidum*. In the presence of concurrent HIV infection, syphilis has been thought to (1) progress more frequently and rapidly to neurosyphilis,<sup>519,520</sup> (2) lead to an increased incidence of meningitic manifestations of neurosyphilis,<sup>521</sup> (3) lead to an increased frequency of “malignant secondary syphilis” with ulcerating lesions and prominent systemic symptoms,<sup>522</sup> and (4) be less amenable to successful therapy with standard regimens as assessed by clinical or serologic measures (including a lack of appropriate nontreponemal titer reduction or a serologic relapse).<sup>523–527</sup> Such concerns, based largely on case reports and retrospective studies, were amplified by the disconcerting finding of *T. pallidum* invasion of the CNS in early syphilis in HIV-infected patients. Such early invasion of the CNS occurs equally frequently in HIV-seropositive and -seronegative people, however,<sup>528</sup> and the “atypical” courses of syphilis described previously were well-known in the pre-AIDS era. Knowledge of the actual frequency and relative significance of such events has awaited well-designed prospective studies. Three studies now provide evidence that the clinical presentation and clinical and serologic responses to treatment of syphilis may not be appreciably altered by HIV coinfection.<sup>529–531</sup> A major caveat of these studies is that the mean level of

immunosuppression in the patients in these studies, as assessed by CD4+ T-cell counts, was not severe. Furthermore, the number of patients involved was relatively small. Thus, the clinical course of syphilis in the face of severe HIV-induced immunosuppression may in fact be exacerbated, and the response to conventional therapy may lead to the infrequent occurrence of serious adverse treatment outcomes.<sup>531</sup> The clinical approach to the HIV patient infected with this cosmopolitan sexually transmitted disease (STD) has been thoroughly discussed elsewhere<sup>76–79,532,533</sup> and will likely continue to evolve.

Whether HIV infection has a deleterious effect on the course of the nonvenereal, endemic treponematoses (see Chapter 44) is unknown, but such an effect has been postulated by analogy with syphilis.<sup>534</sup> No effects of HIV on concurrent infection with the *Borrelia* species that cause relapsing fever have been reported (see Chapter 45). Whether Lyme disease follows an unusual course in HIV-infected people is unclear.<sup>535,536</sup> Finally, initial observations suggest that leptospirosis (see Chapter 46) runs a similar course in patients coinfecting with HIV.<sup>537,538</sup>

### Rickettsial and Ehrlichial Infections

Among the rickettsiae and related organisms, only *Coxiella burnetii* and *Ehrlichia* organisms have been suspected of being exacerbated by concurrent HIV infection. Notably, these pathogens are obligate intracellular parasites of monocyte/macrophages.

Q fever (see Chapter 54) has a worldwide distribution. The responsible pathogen, *C. burnetii*, lives and multiplies in the phagolysosomes of monocyte/macrophages. As with other such parasites, host defense against infection appears to depend on specific T-cell activation of the microbicidal effector functions of infected cells.<sup>539</sup> Radiation, cyclophosphamide, corticosteroids, and pregnancy have led to reactivation of disease in animal models.<sup>539</sup> Case series have suggested that patients with immunocompromise due to a variety of causes (including leukemia, Hodgkin's disease, bone marrow and renal transplantation, and alcoholism) are more susceptible to both symptomatic acute and relapsing or chronic disease with *C. burnetii*.<sup>540–542</sup> The rationale for expecting more frequent or serious disease in the HIV-infected patient is clear. The data are less so. A study from southern France demonstrated a threefold higher prevalence of antibodies to *C. burnetii* in HIV-seropositive people.<sup>543</sup> This suggestion of an increased rate of transmission in HIV-infected people has not been found in other seroprevalence studies from Paris, Spain, or the Central African Republic.<sup>544–546</sup> Given the differential prevalence of risk factors for the acquisition of HIV infection between the studies, the contradictory data strongly suggest that *C. burnetii* can be blood-borne and that intravenous drug use is a risk for its transmission. Two studies from southern Europe have further suggested that HIV infection leads to a higher disease-infection ratio with *C. burnetii*.<sup>543,547</sup> A retrospective serologic study of 520 patients with acute Q fever from an area of Spain with a high incidence of both HIV and *C. burnetii* infection revealed no overrepresentation of HIV-infected people, however.<sup>546</sup> The clinical features of Q fever do not appear to vary between HIV-infected and -uninfected hosts.<sup>543,545–547</sup> However, definitive statements await prospective studies in severely immunosuppressed AIDS patients.

Human monocytic ehrlichiosis (HME), caused by the tick-borne *Rickettsia*-like agent *E. chaffeensis*, is an acute febrile illness associated with leukopenia, thrombocytopenia, and hepatic enzyme abnormalities. Most case reports of infection with *E. chaffeensis* (see Chapter 53) have been from the United States. A report of infection in Mali supports a much wider distribution of disease, however.<sup>548</sup> HME appears to be an AIDS-related OI.<sup>549</sup> Reported hospitalized cases have had a high rate of complications and a mortality of approximately 30%<sup>549</sup> (compared with an estimated case fatality rate for HME in the absence of HIV of <3%<sup>550</sup>). Patients with fatal disease had CD4+ T-cell counts less than 200/ $\mu$ L; in patients with less than 100/ $\mu$ L, the mortality rate was more than 50%. Of eight reported cases of disease caused by *E. ewingii*, a related tick-borne agent, seven occurred in patients with immune deficiencies, including four with HIV infection.<sup>549,550</sup> The suspicion is thus strong that *E. ewingii* is an opportunistic pathogen in the setting of HIV infection.<sup>551</sup> No cases of infection with the tick-borne agent of human granulocytic ehrlichiosis<sup>552</sup> in the face of HIV infection appear to have been reported.

There is no evidence implicating any of the spotted fever or typhus group of rickettsiae as having a clinically significant interaction with HIV. Although neither the mortality nor the morbidity of Rocky Mountain spotted fever are changed by HIV coinfection, this infection should not be overlooked in favor of defined OIs in the differential diagnosis of febrile illness in HIV-seropositive patients. A prospective study on scrub typhus [due to *Orientia* (formerly *Rickettsia*) *tsutsugamushi*] revealed no increase in clinical severity at time of presentation in HIV-infected patients with a median CD4+ T-cell count of 70/ $\mu$ L.<sup>553</sup> Interestingly, rickettsemia occurred significantly less often in the HIV-seropositive patients. Neither the relative prevalence of infection nor the response to treatment was addressed in this study.

### Bacterial Infections

#### *Brucella*

A cause of systemic disease worldwide, *Brucella* species are facultative intracellular parasites that infect and multiply in macrophages (see Chapter 41). CMI responses, particularly the activation of monocyte/macrophages by antigen-specific T cells, are important in host resistance. Despite this, the meager published data on coinfection do not support a significant effect of HIV on infection with *Brucella* and, in fact, prior to the AIDS pandemic, only two cases of brucellosis in immunocompromised hosts (hairy cell leukemia and IgM deficiency) had been reported.<sup>554,555</sup> A retrospective seroprevalence study found no significant association between *Brucella* serology and HIV serology in a cohort of female sex workers in Kenya.<sup>556</sup> The prevalence of antibodies to each pathogen was high (HIV, 65%; *Brucella*, 35%). The clinical course of brucellosis in the 18 reported cases with concurrent HIV infection was not outside the spectrum of disease seen in normal hosts.<sup>556–560</sup> Definitive data on the interaction between these two pathogens await careful prospective studies.

#### *Burkholderia pseudomallei*

Melioidosis (see Chapter 34) does not appear to behave as an AIDS-related OI. The disease is endemic in Southeast Asia,

particularly in northern Thailand, where the prevalence of AIDS is high. Only one case of fatal, recrudescing, bacteremic disease in an HIV-seropositive person has been reported, however.<sup>561</sup> Clinical series from Thailand are silent with regard to the presence of melioidosis in AIDS patients,<sup>374,375,561–563</sup> and a 10-year study of bloodstream infections in a hospital in northern Thailand reported a similar proportion of *B. pseudomallei* isolates in HIV-infected and -uninfected patients.<sup>564</sup>

### Enteric Bacteria

Several enteric bacterial infections have been reported to cause disease of greater severity, invasiveness, chronicity, or recurrence in the presence of HIV coinfection. Enterotoxigenic *E. coli* has not been described as causing more severe disease in HIV-seropositive patients, but *Shigella* species, *Salmonellae*, *Campylobacter*, and *Listeria monocytogenes* have all been implicated as causes of more severe or relapsing disease in the presence of HIV. Data from the tropics on enteric bacterial pathogens are scant. Studies of slim disease (enteropathic AIDS) have not revealed an enteric bacterial cause in most cases.<sup>304,458,459</sup> The prevalence of certain enteric pathogens such as *Campylobacter*, vibrios, and enteropathogenic *E. coli* in the tropics has not been accurately assessed because their detection requires the use of special media and experienced laboratory personnel. In the case of less fastidious organisms that are easier to detect, such as *Salmonella* spp., the phenomenon of bacteremia with nontyphoid organisms has been noted in tropical Africa.<sup>29</sup> Since bacteremia with *Shigella* spp. probably occurs more commonly in patients with HIV disease,<sup>565</sup> this association may be expected to occur in the tropics as well. There is no reported evidence to suggest that cholera is altered in the presence of HIV, although the gastric secretory failure that occurs commonly in AIDS may lead to a greater susceptibility to infection to *Vibrio cholerae*.<sup>566,567</sup> It should be noted that although the live oral cholera vaccine is considered to be contraindicated in people with HIV infection by the USPHS–IDSA working group,<sup>213</sup> it has been shown to be safe and immunogenic in HIV-infected adults in Mali.<sup>568</sup> Further details on the association of HIV and enteric bacterial infections, including therapy, are presented in Chapters 16 through 21 and in reviews elsewhere.<sup>76,77</sup>

### Other Bacteria

Although the data on HIV infection and epidemic meningococcal meningitis have not provided evidence for a significant interaction,<sup>569</sup> studies suggest that HIV infection may be a risk factor for sporadic meningococcal disease.<sup>570,571</sup> Interactions between HIV and *Bacillus anthracis* or *Yersinia pestis* have not been reported. The globally endemic *Bartonella* species, *Bartonella henselae* and *Bartonella quintana* (see Chapter 40), cause acute and persistent bacteremia as well as localized tissue infection (including bacillary angiomatosis, bacillary peliosis, microscopic abscess formation, and lymphadenitis), primarily in AIDS patients and other immunocompromised people.<sup>572</sup> The closely related species *Bartonella bacilliformis*, which is geographically restricted to Andean river valleys, causes a similar spectrum of disease (including acute and persistent bacteremia and hemangiomatous nodules resembling those seen in bacillary angiomatosis) in

immunologically normal hosts (see Chapter 40). Cases of coinfection with HIV and *B. bacilliformis* do not appear to have been reported.

## Viral Infections

### Hemorrhagic Fever Viruses, Arboviruses, and Others

None of the viruses that, along with parasites, have formed the traditional focus of the Anglo-American specialty of tropical medicine have been reported to cause uniquely prevalent, severe, or unusual disease in people infected with HIV. No significant interactions have been well documented between HIV and bunyaviruses, hantaviruses, phleboviruses, arenaviruses, alphaviruses, or filoviruses. In part, of course, this may be a function of a lack of sufficient experience with coinfection with these agents. Among the flaviviruses, (1) two uncontrolled series of patients with St. Louis encephalitis in Texas have suggested the possibility that the ratio of disease to infection, but not the course of symptomatic disease, is worsened in the presence of HIV infection,<sup>573,574</sup> and (2) there are insufficient data to determine whether HIV alters the course of yellow fever (no case reports; 20% to 50% mortality in the absence of coinfection<sup>575</sup>), West Nile virus infection (single case report<sup>576</sup>), or dengue infection (single case report<sup>577</sup>). Interestingly, the case report of dengue coinfection suggests that dengue fever, like acute measles and scrub typhus, may lead to a reversible suppression of HIV replication.<sup>577</sup>

Should the live-attenuated yellow fever vaccine be given to those infected with HIV? There are theoretical risks of vaccine-induced encephalitis and/or hepatic damage due to prolonged viremia in the immunodeficient.<sup>575</sup> A handful of cases of post-vaccinal encephalitis or multiple organ failure (yellow fever vaccine-associated viscerotropic disease [YEL-AVD]) have been reported in presumably immunocompetent patients (against a denominator of approximately 400 million people vaccinated).<sup>575</sup> Of note, 4 of 23 vaccinees who developed YEL-AVD had undergone thymectomy for thymomas, raising the concern that deficient thymic function may permit fatal vaccine-induced viral infections.<sup>578</sup> A single case has also been reported of fatal myeloencephalitis after vaccination in a Thai man with asymptomatic HIV infection, albeit a low CD4+ T-cell count and a high viral load.<sup>579</sup> Approximately 100 asymptomatic HIV-seropositive U.S. military personnel received yellow fever vaccination prior to the introduction of routine HIV screening; no adverse effects were detected (R. Redfield, personal communication, 1997). Small published series of travelers have suggested safety and variable efficacy of the 17D yellow fever vaccine in HIV seropositives without severe immunosuppression.<sup>580–582</sup> The immunogenicity of yellow fever vaccination has been noted to be severely reduced, again in the absence of significant adverse events, in HIV-infected children in Côte d'Ivoire<sup>583</sup> (T. Tsai, personal communication, 1997). WHO recommendations are to use yellow fever vaccine in HIV-seropositive patients who are asymptomatic. It remains a part of the WHO EPI.<sup>443</sup> Pending further studies, yellow fever vaccine is not recommended for symptomatic HIV-infected patients by WHO.<sup>443</sup> The ACIP recommends that HIV-infected people without AIDS or other symptomatic manifestations of HIV infection, who have laboratory-established verification of adequate immune function,

and who cannot avoid potential exposure to yellow fever be offered the choice of vaccination.<sup>584</sup> Given apparent reduced vaccination efficiency, neutralizing antibody titers should probably be measured prior to travel. If travel requirements (as opposed to actual risk of infection) are the only reason for vaccination of an asymptomatic HIV-infected person, a vaccination waiver letter (which may not be accepted at some borders) should be obtained.<sup>584</sup> For all travelers, avoidance of areas of transmission and, if travel to such areas is essential, conscientiously avoiding mosquito exposure is prudent.

## Measles Virus

Measles virus (see Chapter 55) causes an annual mortality in the tropics far in excess of that due to the “traditional” tropical disease viruses. In fact, the worldwide yearly mortality due to measles is rivaled among single pathogens only by falciparum malaria, tuberculosis, and AIDS. This mortality is predominantly in sub-Saharan Africa. Similar to AIDS, infection with measles virus is accompanied by marked abnormalities of CMI that contribute to the increased susceptibility to secondary infections that account for much of the morbidity and mortality of the disease.<sup>585–589</sup>

Measles is exacerbated in the presence of HIV coinfection.<sup>590–602</sup> The mortality rate in North American case series and reports of measles in HIV-positive children and adults has been 40%, far higher than the usual 0.1% case fatality rate seen in the United States.<sup>509–599</sup> Although the presentation of disease has been normal in many, up to 40% have had no rash. In these reports, giant cell pneumonitis has been the principal complication and the prime cause of death, although fatal subacute measles encephalitis has also been described. CD4+ T-cell counts have not been reported in many of these cases, but where they have been reported they have generally been less than 500/ $\mu$ L. Such case reports and series are obviously likely to be biased toward the severe end of the spectrum of disease, however. Three substantial studies have investigated HIV–measles coinfection in sub-Saharan Africa.<sup>600–602</sup> A study of children hospitalized with measles in Kinshasa showed similar mortality rates among HIV-seropositive (31.3%) and -seronegative (28%) children.<sup>600</sup> The fact that only severely ill patients, with complications, were hospitalized likely obviated the ability to detect differential mortality in this study. An initial study of children with measles in Lusaka revealed a significantly higher mortality rate in HIV seropositives (28%) than seronegatives (8.3%).<sup>601</sup> A second prospective study in hospitalized children in Lusaka that distinguished between HIV infection and HIV seropositivity found few differences in the clinical presentation, complications, or mortality of HIV-infected compared to -uninfected children with measles.<sup>602</sup> However, enrollment was based on a clinical diagnosis of measles, which would be expected to minimize the ability to detect differences in clinical presentation; there was a bias against enrollment of critically ill children and those dying soon after admission; and there was significantly greater mortality among HIV-infected compared with -uninfected children among those with clinically diagnosed as opposed to confirmed measles.<sup>602</sup> Early death prior to mounting diagnostic measles IgM titers in the face of severe immunosuppression was suspected to be confounding. Other positive findings in this study included a higher proportion of

HIV infection among children hospitalized with measles than expected from (maternal) population prevalence rates, a greater proportion of coinfecting patients hospitalized with measles younger than the age of 9 months, and a longer duration of illness before hospitalization and longer hospitalization in coinfecting children.<sup>602</sup> Follow-up studies have shown that coinfecting patients have a higher risk (90.9% vs. 52.8%) for prolonged (30 to 61 days after rash onset) shedding of measles virus<sup>603</sup>; and that in vivo HIV replication appears to be suppressed during acute measles.<sup>604</sup>

No therapies have been rigorously studied. Vitamin A, which has been shown to be protective in severe measles in malnourished children,<sup>605</sup> may be of benefit, especially given the marginal nutritional status of many with HIV infection. Ribavirin has been shown to reduce the severity of measles in normal hosts.<sup>606</sup> Reports of its use in HIV-positive patients with measles pneumonitis have suggested some efficacy, although rigorous data are lacking.<sup>591,592,594,595,598</sup> Intravenous use is probably most effective. Intravenous immune globulin (IVIG) may also be of benefit.<sup>592</sup>

Given the severity of measles in HIV patients, prevention is key. Postexposure prophylaxis with intramuscular immune globulin attenuates disease in normal hosts. It is recommended by the ACIP<sup>607</sup> in symptomatic HIV patients (and in those with CD4+ T-cell counts <200/ $\mu$ L) regardless of measles serostatus, but it may have limited efficacy in these and other immunosuppressed patients.<sup>595,608</sup> The recommended dose is 0.5 mL/kg (15 mL maximum), given intramuscularly within 6 (or, better, 3) days. Such postexposure prophylaxis is also recommended by the American Academy of Pediatrics (AAP) for all HIV-infected children and adolescents, and for all children of unclear infection status born to HIV-infected women, regardless of measles immunization status or degree of immunosuppression.<sup>609</sup> Preexposure prophylaxis with monthly IVIG has been advocated for HIV-positive children with documented measles vaccine nonresponsiveness during community outbreaks of measles,<sup>595</sup> but this is not likely to be an economically viable option in the resource-poor areas of the tropics where measles is heavily endemic.

Vaccination remains the principal strategy for preventing measles in HIV-infected people. In normal hosts, the protective efficacy of measles vaccination is greater than 95%.<sup>610</sup> Vaccination efficacy data in HIV-seropositive people is lacking, but seroconversion data are available. This is a less than ideal surrogate. In general, there is a strong correlation between levels of neutralizing antibody and protection, but the failure of postexposure prophylaxis with immune serum globulin in preventing fatal giant cell pneumonia in patients with the cellular immunodeficiencies noted previously provides compelling evidence that CMI mechanisms, whether specific or nonspecific, are important even in protection from initial infection. In adults with HIV infection, there appears to be no waning of measles antibody titers with increasing immunosuppression.<sup>611–613</sup> Unfortunately, there are no clear data on the response to vaccination in those adults who lack antibodies to measles.<sup>614</sup> In children, the situation is different. HIV-infected infants have a markedly lower rate of seroconversion after measles vaccination, generate lower titers of antibody on seroconversion, and have a high rate of secondary vaccine failure, with antibody titers that decrease with time and with increasing immunosuppression.<sup>615</sup> Variable, but

generally poor, responses to second doses of vaccine have been reported.<sup>615</sup>

There may be a benefit to vaccinating early (at 6 to 9 months of age) to take advantage of the fact that there is less HIV-related immunosuppression at this early age. Early vaccination may also be valuable because both HIV-positive and HIV-negative infants born to HIV-infected mothers have lower titers of maternal antimeasles antibody.<sup>616</sup> In a study in Kenya, the risk of acquiring measles before vaccination at 9 months of age (the standard age of vaccination in Africa at the time) was 3.8 times higher (95% confidence interval, 1.2 to 13.2) in infants born to HIV-seropositive mothers.<sup>616</sup> High-titer measles vaccines may be more immunogenic in HIV-infected children<sup>617,618</sup> but have been discontinued for safety reasons in all children.

Safety concerns have obviously been of great importance in the use of this live-attenuated vaccine in HIV patients. Although the use of measles vaccine had appeared to be quite safe in HIV-infected children and adults,<sup>619</sup> two reports have emphasized the need for some caution. A 20-year-old man with no HIV-related symptoms but a CD4+ T-cell count “too few to enumerate” received a second dose of measles vaccine prior to entry into college. One year after vaccination, he developed progressive, vaccine-associated measles pneumonitis.<sup>620</sup> A study of the effect of HIV on measles mortality in 356 children hospitalized with measles in Lusaka, Zambia, is also troubling.<sup>601</sup> Previous studies have suggested that when prior measles vaccination does not prevent disease, it can reduce the severity of infection.<sup>600</sup> In HIV-seronegative boys hospitalized for measles, prior measles vaccination did lead to a significantly lower case fatality rate.<sup>601</sup> Although case fatality rates were not significantly lower in vaccinated HIV-seropositive boys or HIV-seronegative girls than in their unvaccinated controls, there was a trend toward a lower case fatality rate in the vaccinees. Surprisingly, however, the case fatality rate was higher in measles-vaccinated than in unvaccinated HIV-seropositive girls. Although this did not reach statistical significance, it is reminiscent of the experience with the high-titered Edmonston–Zagreb (EZ) vaccine. Use of high-titered EZ vaccine at less than 9 months of age was associated with a delayed excess mortality in several study sites.<sup>621–623</sup> This occurred exclusively in female infants for reasons that remain unclear. It is notable that in the Zambian study noted previously, the highest mortality was seen in the youngest, vaccinated HIV-seropositive girls. However, in regions where there is measles transmission, risk–benefit analysis clearly favors measles immunization of all children regardless of HIV status.<sup>615</sup> In regions where measles transmission does not occur and where immune status can be monitored, withholding of measles vaccine from HIV-infected children with severe immune compromise is wise.<sup>615</sup> WHO recommends measles vaccination for all children in developing countries regardless of HIV infection or symptom status because of the high risk and severity of measles in general in such countries.<sup>443,624</sup>

In the United States, the USPHS–IDSA working group and the ACIP recommend measles vaccination for HIV-infected people according to the schedule and conditions for normal hosts if they are not severely immunocompromised.<sup>213,610</sup> In addition, the risks and benefits of vaccination or immune globulin prophylaxis should be weighed in severely immunocompromised patients who are at increased risk due to travel

or outbreaks.<sup>213,607</sup> AAP recommendations for HIV-infected infants to young adults in the United States include

- No immunization in the face of severe immunosuppression
- Use of the measles–mumps–rubella (MMR) vaccine at 12 months of age, with a second dose given as soon as 28 days after the first dose
- With measles transmission in the community, vaccination of infants as young as 6 months old with MMR or monovalent measles vaccine, and revaccination with MMR at 12 months
- Vaccination of all measles-susceptible household members of an HIV-infected person
- Use of immune globulin prophylaxis as noted previously<sup>609</sup>

Few data are available on other paramyxoviruses in AIDS. With respiratory syncytial virus infection, pneumonia may be more common than bronchiolitis with wheezing, and viral carriage may also be prolonged.<sup>625–628</sup> Copathogens may occur more frequently than in normal hosts.<sup>626</sup> Ribavirin appears to be efficacious in both children and adults.

## Rabies

Most human rabies (see Chapter 75) occurs in tropical countries where canine rabies is still endemic. The presentation of rabies does not appear to be altered by HIV infection.<sup>629</sup> HIV-infected children and adults clearly have substandard responses to rabies vaccination, however.<sup>630–632</sup> WHO recommendations for postexposure prophylaxis in the face of HIV infection include mandatory use of rabies immune globulin, use of intramuscular vaccine, and monitoring of neutralizing antibody titers.<sup>633</sup> Revaccination may be necessary. Even multiple-site, double-dose postexposure vaccination has led to poor responses in the face of HIV coinfection.<sup>632</sup>

## Poliomyelitis

Great strides have been made in worldwide polio eradication (see Chapter 60). Most of the remaining burden of poliomyelitis is in the tropics outside the Western Hemisphere. There is no evidence that HIV infection alters the outcome of infection with poliovirus. It has been estimated that more 500,000 HIV-infected children have received live oral polio vaccine (OPV).<sup>615</sup> Only two cases of vaccine-associated paralytic poliomyelitis in HIV-infected children have been reported.<sup>615</sup> If there is greater risk of vaccine-associated disease in the face of HIV infection, the attributable risk is thought to be very low.<sup>615</sup> OPV remains part of the WHO EPI for all children.<sup>443</sup> In the United States, the OPV is supported by the ACIP as the only vaccine recommended for polio eradication where there still is transmission of wild-type polio.<sup>634</sup> ACIP recommendations have replaced OPV with inactivated polio vaccine for all vaccinees in the United States.<sup>634</sup>

## Other Enteric Viruses

Chronic diarrhea is a common problem in AIDS patients throughout the world. Although no definite pathogenic role has been ascribed to enteric viruses (small round structured viruses, enteric adenoviruses, and coronaviruses) in AIDS-related diarrhea in either North America or Africa,<sup>635,636</sup> there

are some preliminary data suggesting greater disease severity in children coinfecting with HIV and astroviruses<sup>637</sup> and an association of picobirnaviruses with diarrhea in HIV-coinfecting patients.<sup>638</sup> In non-cholera-endemic areas of the tropics, rotavirus is probably the principal cause of diarrheal deaths in HIV-uninfected infants.<sup>639</sup> Rotavirus diarrhea does not appear to be an opportunistic pathogen in children with HIV coinfection. In a large study in Malawi, no differences in the severity of rotavirus gastroenteritis were found between HIV-infected and -uninfected children.<sup>640</sup> Interestingly, rotavirus was less frequently detected in HIV-infected children with gastroenteritis. Despite equal resolution of clinical disease, however, the frequency of death after hospital discharge was significantly greater in coinfecting children.<sup>640</sup>

## Hepatitis Viruses

Infection with hepatitis A virus (HAV) (see Chapter 64) occurs worldwide. In resource-poor countries, especially in the tropics, HAV is hyperendemic, and exposure to the virus (usually subclinical) is essentially universal by the age of 10 years. Virtually all adults are immune. HIV/HAV coinfection appears to be associated with a higher HAV serum viral load, a longer duration of viremia, and lower elevations in serum alanine aminotransferase levels<sup>641</sup> but a similar disease course.<sup>641–643</sup> Vaccination against HAV is safe in HIV-infected patients.<sup>644–646</sup> Efficacy wanes with increasing immunosuppression.<sup>645,646</sup> Some recommend vaccination for all those at risk (defined by a negative serology).<sup>76</sup>

Infection with hepatitis E virus (HEV) (see Chapter 64) is more localized, with sporadic and epidemic disease being reported in Mexico; North and West Africa; the Middle East; and South, Southeast, and East Asia. Clinical disease occurs in both adults and children. HEV has not been implicated as having any significant interaction with HIV.

With the cosmopolitan hepatitis viruses that are capable of causing chronic disease, however, several potentially important interactions with HIV have been described. The prevalence of coinfection is furthered by the fact that these viruses share routes of transmission with HIV. For hepatitis B virus (HBV) (see Chapter 64), CMI responses are thought to be important both for the resolution of acute disease and for the production of hepatic inflammation in chronic disease. HIV infection has been reported to lead to

- At least a threefold increase in risk of the development of a chronic HBV carrier state (with an inverse correlation with the CD4 count), without a significant change in the severity of acute disease<sup>647,648</sup>
- Potential reactivation of quiescent HBV infection<sup>649,650</sup>
- Increased HBV replication and decreased inflammation in those with<sup>647,649</sup> or without<sup>651</sup> chronic hepatitis
- A decreased response to HBV vaccination<sup>652</sup>
- Loss of HBV antibody over time<sup>652,653</sup>
- A 15-fold increase in liver-related mortality in HBV-infected individuals<sup>654</sup>

Vaccination against HBV has reasonable efficacy in HIV-seropositive populations. Interestingly, however, the highest reported rate of development of the chronic carrier state in adults (56% to 80%) occurred in HIV-infected people who were vaccinated at the same time that they developed HBV infection.<sup>648</sup> HBV does not appear to have a significant effect on the clinical course of HIV infection.<sup>655</sup>

With hepatitis C virus (HCV) infection (see Chapter 64), HIV coinfection is associated with an increased risk of progression to chronic infection.<sup>656</sup> Documented interactions between the two viruses<sup>657</sup> include (1) an increase in HCV viral load<sup>658,659</sup>; (2) an increase in vertical<sup>660</sup> and male-to-female sexual transmission<sup>659</sup> of HCV, probably due to higher viral load; (3) a more severe clinical and histopathologic course<sup>661,662</sup>; and (4) a high percentage of indeterminate HCV immunoblot assays, with frequent HCV seroreversion.<sup>656</sup> Whether HCV infection has a significant effect on the natural history of HIV infection or the response to HAART therapy remains controversial.<sup>663–667</sup> Maternal HCV infection appears to be associated with an increased risk of HIV vertical transmission.<sup>668</sup> Treatment of both HIV/HCV and HIV/HBV infection has been reviewed recently.<sup>657</sup>

The data on hepatitis D virus (HDV) are more meager. HDV replication may be prolonged or reactivated in the presence of HIV coinfection.<sup>669,670</sup>

## Herpesviruses

As in the industrial world, herpes zoster is quite common in adult AIDS patients in the tropics. A history of shingles is reported by more than 10% of AIDS patients in Africa.<sup>671</sup> In areas of Africa with a high seroprevalence for HIV, the positive predictive value of a history of shingles for HIV infection is greater than 90%.<sup>671</sup> As elsewhere, zoster tends to develop early in HIV disease, and recurrence is common.<sup>671,672</sup>

Chronic genital herpes simplex lesions are common throughout the world in patients with sexually transmitted HIV infection. CMV infection is ubiquitous in most of the tropics.<sup>673</sup> The reported incidence of severe disease due to CMV in AIDS in Africa and Asia (although not Latin America and the Caribbean) has lagged behind that of the industrial north, however, likely because of greater mortality at earlier stages of disease.<sup>674,675</sup> The natural history, diagnosis, and therapy of disease due to coinfection with these cosmopolitan herpesviruses have been discussed elsewhere.<sup>76–79</sup>

Endemic (central Africa), AIDS-related, “classic,” and post-transplant Kaposi’s sarcoma are all closely associated with human herpesvirus 8 (HHV8) (see Chapter 57).<sup>676</sup> In the AIDS era, Kaposi’s sarcoma has become one of the leading malignancies in areas of sub-Saharan Africa.<sup>677</sup> The epidemiology, clinical manifestations, and therapy of HHV8 infection and Kaposi’s sarcoma (a disease that the industrialized world had considerable experience with early in HIV pandemic) have been reviewed elsewhere.<sup>76,77,678,679</sup>

## Other Viruses

Although data remain somewhat limited, the cosmopolitan influenza virus appears to cause more severe disease in HIV coinfecting patients, with prolongation of symptoms and a higher risk for complications, hospitalization, and death.<sup>680</sup> Influenza vaccination is safe and recommended by the ACIP for HIV-infected patients.<sup>680</sup> Such vaccination has been shown to have good efficacy in a study in individuals with a mean CD4+ T-cell count of 200/ $\mu$ L.<sup>681</sup> With advanced HIV, vaccination may not generate protective antibody titers.<sup>682</sup>

The single case report of severe acute respiratory syndrome (SARS) coronavirus infection in the face of HIV coinfection was within the described clinical spectrum of this newly emerging virus.<sup>683</sup>

## SPECIAL ISSUES

### HIV and Eosinophilia

The association of blood (or tissue) eosinophilia with tissue exposure to helminthic parasites can be of considerable diagnostic utility in non-HIV-infected populations (see Chapter 125). Data suggest that this utility may be lessened by the presence of HIV infection. Both relative and absolute eosinophilia occur for nonparasitic reasons with considerable frequency in HIV-infected populations. A relative eosinophilia commonly occurs with progressive HIV disease, at least in North American adult AIDS patients,<sup>684,685</sup> due to a sparing of absolute blood eosinophil concentrations in the face of decreasing concentrations of all other granulocytic and mononuclear leukocyte populations.<sup>685</sup> This effect becomes marked with CD4+ T-cell counts less than 200/ $\mu$ L.<sup>685</sup> Nonhelminth-related absolute eosinophilia also occurs with regularity with advancing HIV disease. Absolute eosinophilia in North American HIV-seropositive adults has most frequently been associated with pruritic cutaneous disease, particularly the diagnoses of eosinophilic pustular folliculitis, atopic dermatitis, and prurigo nodularis.<sup>686</sup> Most such patients have CD4 counts less than 100/ $\mu$ L.<sup>686</sup> It remains unclear in these patients whether the eosinophilia is primary with secondary cutaneous manifestations or an allergic response to a predominantly cutaneous antigen. A few AIDS patients have presented with what appears to be a variant of the hypereosinophilic syndrome with prominent cutaneous manifestations<sup>687,688</sup> or a hyper-IgE-like syndrome.<sup>689</sup> Rare causes of tissue or blood eosinophilia in AIDS patients have included acute eosinophilic pneumonia<sup>690</sup> and high-grade B-cell lymphomas.<sup>691</sup> Adverse reactions to various prophylactic and therapeutic agents may also elicit eosinophilia in AIDS patients. Other causes of secondary blood eosinophilia appear to be quite uncommon in North American AIDS patients.<sup>691</sup> This includes adrenal insufficiency, despite the high prevalence of adrenalitis at autopsy in AIDS patients.<sup>692</sup> The upshot of these reports is that the diagnostic specificity of blood eosinophilia for tissue helminthic infection is probably poorer in HIV-infected than in HIV-free adult patients in the industrial north (a conclusion somewhat undermined by the low population prevalence of helminthic disease in the studies cited previously). It is probably reasonable, however, to avoid an extensive workup for parasitic and other causes of eosinophilia in adult eosinophilic AIDS patients with cutaneous disease from the industrial world; however, in populations at higher risk of helminthiasis, such a conclusion is unwarranted in the absence of prospective studies of eosinophil levels in AIDS patients with tissue helminthiasis.<sup>693</sup> Such eosinophilia with advancing HIV disease has not been noted in children in the industrial world.<sup>694,695</sup>

The data from the tropics are dramatically at variance with the reports from the industrial world. A study of patients with tuberculosis in Burkina Faso reported lower eosinophil levels in HIV-seropositive people compared with seronegative people, with a strong correlation between CD4+ T-cell and eosinophil counts.<sup>696</sup> A follow-up study in Faso reported that in helminth noninfected HIV patients, eosinophil counts were higher in CDC stage B patients than in controls but were severely decreased in CDC stage C patients.<sup>697</sup> Mean eosinophil counts in a cohort of 611 HIV-infected patients in Cote d'Ivoire, with a mean CD4+ T-cell count of 115 cells/ $\mu$ L, were in the normal range for HIV-uninfected populations in areas of the world with a low

prevalence of helminth infection.<sup>698</sup> Finally, a case report from England of HAART-related immune reconstitution in a schistosomiasis-infected woman from southeast Africa is intriguing.<sup>699</sup> The patient presented with a CD4+ T-cell count less than 200/ $\mu$ L and an eosinophil count of 300/ $\mu$ L. Immune reconstitution was accompanied by the development of robust eosinophilia (1500/ $\mu$ L) that decreased with praziquantel treatment. Taken together, these findings suggest that late HIV disease in the tropics, as opposed to the industrial world, is associated with a suppression of blood eosinophil levels. The mechanism(s) responsible for these divergent findings remains unclear.

### Prevention of Opportunistic Infections

The USPHS–IDSA working group has updated guidelines for preventing OIs in HIV-infected people in industrialized countries.<sup>213</sup> The data on 19 OIs frequent in North American HIV-infected populations were reviewed. Factors considered in these evaluations were

- Disease incidence
- Disease severity in terms of morbidity and mortality
- The level of immunosuppression at which disease is most likely to occur
- The feasibility, efficacy, and cost of preventive measures
- The impact of intervention on quality of life
- Toxicities, drug interactions, and the potential for drug resistance
- The quality of the evidence supporting each recommendation<sup>213</sup>

The prevention of each OI was evaluated from the standpoint of prevention of exposure, prevention of the first episode of disease by immuno- or chemoprophylaxis (primary prophylaxis), prevention of disease recurrence (secondary prophylaxis), and discontinuance of prophylaxis in those whose CD4+ T-cell counts had risen in response to HAART.<sup>213</sup>

Specific recommendations for prevention of exposure were made for several agents, including *T. gondii*, *C. parvum*, *M. tuberculosis*, bacterial enteric agents, *Bartonella*, herpes simplex virus (HSV), varicella zoster virus (VZV), CMV, HHV8, human papillomavirus, and HCV.<sup>213</sup> For adults and adolescents, prophylaxis to prevent the first episode of opportunistic disease was strongly recommended as a standard of care for *P. carinii*, *M. tuberculosis* (in the face of tuberculin skin test reactivity or contact with a case of active tuberculosis), *T. gondii*, *M. avium* complex, and VZV (with exposure to chickenpox or shingles in patients without a history of such, or with negative serologies for VZV [varicella Zoster immunoglobulin (VZIG)]). Primary prophylaxis against HBV, HAV, influenza virus, and *S. pneumoniae* was generally recommended. Although evidence exists for efficacy, primary prophylaxis against *C. neoformans*, *H. capsulatum*, CMV, and bacterial infection (in the face of neutropenia) was not routinely recommended. For two of these agents (*P. carinii* and *M. avium*), primary prophylaxis has been shown to confer a survival benefit.<sup>700,701</sup> Secondary prophylaxis to prevent recurrent disease was strongly recommended as the standard of care for *P. carinii*, *T. gondii*, *M. avium* complex, CMV, *C. neoformans*, *H. capsulatum*, *C. immitis*, and nontyphi *Salmonella* species. Such prophylaxis was recommended for HSV and *Candida* only if subsequent episodes are frequent or severe.<sup>213</sup>

For children, primary prophylaxis was strongly recommended as a standard of care for *P. carinii*, *M. tuberculosis*,

*M. avium* complex, and VZV (VZIG); generally recommended for *T. gondii*, VZV (immunization in the absence of immunosuppression), and influenza virus; and recommended only in unusual circumstances for invasive bacterial infection (hypogammaglobulinemia, IVIG), *C. neoformans* (severe immunosuppression), *H. capsulatum* (severe immunosuppression, endemic geographic area), and CMV (CMV antibody positivity and severe immunosuppression). Primary prophylaxis was also addressed through review of the recommendations for routine immunization schedules in HIV-infected children. In addition to standard schedules for immunization against HBV, HAV, polio, *H. influenzae* type b, diphtheria, tetanus, and pertussis, altered schedules for vaccination against *S. pneumoniae* (use of the heptavalent pneumococcal conjugate vaccine beginning at 2 months, followed by 23-valent pneumococcal polysaccharide vaccine at 2 years), influenza (yearly dose recommended), MMR (no administration to severely immunosuppressed children), and VZV (administration only to asymptomatic, nonimmunosuppressed children) were reviewed. Recommendations for secondary prophylaxis were similar to recommendations for adults, with the addition of a recommendation for use of TMP-SMX or IVIG to prevent invasive bacterial infection in the presence of more than two such infections in a 1-year period.<sup>213</sup>

These recommendations are likely to find broad applicability in the industrial world, where the OI spectrum, health-care priorities, and available prevention options are similar. The applicability to much of the tropics is less clear, however, given differing spectra of OIs, differences in antibiotic resistance patterns, and differences in sociocultural acceptability or feasibility of preventive measures. Limits in the availability of health-care resources (including not just an inability to support the cost of many prevention regimens but also an inability to diagnose HIV disease early enough for preventive measures to be effective, to reliably stage the degree of HIV-associated immunosuppression, and to definitively diagnose OIs) also directly influence the range of prevention options and priorities. It should also be noted that compared with HAART therapy (or prevention of HIV infection), the benefit of OI prevention in reducing HIV-related morbidity and mortality may be somewhat modest.<sup>702</sup> Adequate global provision of HAART represents an ongoing, immense challenge, however, and wide implementation of simple, cheap, effective OI prevention strategies provides an opportunity to rapidly and widely reduce morbidity and mortality.<sup>675</sup> The wide availability of affordable and effective regimens may also encourage people to seek HIV testing.<sup>675</sup>

In 1996, Kaplan and colleagues argued that effective research on OI prevention strategies in the tropics will require an integrated approach, including the area-specific determination of OI spectra, determination of environmental reservoirs of opportunistic pathogens and feasible ways to reduce exposure, assessment of immuno- and chemoprophylaxis against such pathogens, and improvement in the ability to identify and inexpensively stage HIV infection.<sup>20</sup> Since then, data on the efficacy of some OI prevention strategies in resource-poor countries of the tropics have accrued.

First, as noted previously, primary preventive therapy against tuberculosis (TB) with isoniazid has been shown to be effective in HIV-infected individuals, regardless of tuberculin status.<sup>423,424,675</sup> WHO and UNAIDS recommendations are for

primary preventive therapy to be given to PPD-positive, HIV-infected individuals who do not have active TB.<sup>425</sup> In settings where it may not be feasible to do PPD testing, the recommendations are for primary preventive therapy to be considered for those living in populations with a prevalence of tuberculous infection estimated to be more than 30%, health-care workers, household contacts of TB patients, prisoners, miners, and other groups at high risk of acquisition or transmission of TB.<sup>425</sup>

Second, TMP-SMX—a cheap, widely available antibiotic with activity against a plethora of OIs (including PCP, nontyphoid salmonellosis, pneumococcal disease, and toxoplasmosis) and malaria—has been shown to reduce morbidity and mortality in HIV-infected adults<sup>675,702–705</sup> and children.<sup>401,706</sup> WHO/UNAIDS recommendations are that TMP-SMX should be used for prophylaxis in adults and children living with HIV/AIDS in Africa as a minimum package of care.<sup>707</sup> For adults in Africa (defined as those older than the age of 13 years), such prophylaxis should be offered to all people with symptomatic HIV disease, those who are asymptomatic with a CD4 count of 500/ $\mu$ L or less (or total lymphocyte equivalent), and pregnant women after the first trimester.<sup>707</sup> WHO/UNAIDS/UNICEF recommendations are that all HIV-exposed children (born to HIV-infected mothers) should get TMP-SMX from the age of 4 to 6 weeks, as should any child identified as HIV infected with any clinical signs or symptoms suggestive of HIV, regardless of age or CD4+ T-cell count.<sup>708</sup> It is further recommended that TMP-SMX should be discontinued (1) in HIV-exposed children only once HIV infection has confidently been excluded (and the mother is no longer breastfeeding); (2) in HIV-infected children on antiretroviral therapy only when evidence of immune restoration has occurred; and (3) in those with severe cutaneous, renal, hepatic, or hematological toxicity.<sup>708</sup> It has been noted that such mass prophylaxis strategies entail some as yet to be quantified risks, principally of increasing rates of drug-resistant bacteria and malaria.<sup>709</sup> Studies to examine such risks should be performed.

Third, a large, randomized, double-blind, placebo-controlled trial of the 23-valent pneumococcal polysaccharide vaccine in HIV-infected Ugandan adults showed no protective effect (with invasive pneumococcal disease as the primary endpoint).<sup>710</sup> Surprisingly, increased rates of pneumococcal disease were seen in vaccine recipients. The potential mechanism(s) remains unclear; not surprisingly, the study remains controversial.

Fourth, among the specifically tropical OIs, a controlled, double-blind trial of primary prophylaxis with itraconazole in Thailand showed efficacy in preventing penicilliosis (and cryptococcosis).<sup>340</sup> There are little or no data available on the prophylaxis of other tropical OIs, such as leishmaniasis and American trypanosomiasis, although the utility of avoiding exposures to the vectors of the agents of these diseases should be clear.

More generally, certain options for preventing or reducing exposure to opportunistic pathogens are likely to be broadly useful, including avoiding unboiled water, raw or undercooked foods, and unpasteurized milk to prevent enteric bacterial and protozoan infections as well as *T. gondii* exposure and also avoiding contact with patients with TB, for example, in patient-care settings. Avoidance of exposure to

the opportunistic agents of disseminated fungal disease is likely to be impractical in most settings.

### The HIV-Infected Traveler in the Tropics

It is clear that for many people, HIV infection is more an inducement than a hindrance to travel.<sup>711</sup> For HIV-infected patients from the industrial world, travel to the tropics leads to an increased risk of exposure to a variety of ubiquitous as well as geographically focal infectious diseases (see Chapter 120). The principal concerns are enteric, respiratory, and vector-borne infections. STDs deserve special mention, however. Despite the AIDS pandemic, studies continue to document a high frequency of unprotected sexual encounters among travelers to the tropics.<sup>712,713</sup> For the HIV-infected traveler, it bears remembering that spread of the AIDS pandemic has been along the routes of human travel and migration.<sup>712</sup> HIV-infected travelers should notify sexual partners of their HIV status, observe safe sex practices, refrain from donating fluids or tissue, inform health-care providers of the need for blood precautions, and avoid the sharing or recreational use of needles. For travelers who are not infected with HIV, pretravel counseling should be given on strategies to minimize the risk of HIV acquisition during travel, including

- Avoiding sex with new partners
- Using latex condoms if having sex (remembering that condom quality varies throughout the world)
- Taking a supply of sterile needles and syringes if routine or frequent injections are required (e.g., for insulin-dependent diabetes) or if a prolonged stay in remote areas is planned
- Avoiding all skin-piercing procedures (e.g., tattooing, acupuncture, and shaving by barbers) and avoiding invasive medical and dental procedures if possible
- Being cognizant of the risks of motor vehicle travel because motor vehicle injuries are not just among the greatest health threats to travelers in the tropics but also provide a major risk factor for needing emergency blood transfusion in countries where HIV screening of the blood supply is not routine

These are also important educational points for HIV-infected travelers.

There are recent reviews of medical issues in the HIV-infected tropical traveler from the industrial world<sup>714,715</sup> and information is available from [www.cdc.gov/travel/hiv\\_travel.htm](http://www.cdc.gov/travel/hiv_travel.htm). Careful, timely pretravel advice and planning can help HIV-infected patients minimize the unavoidable risks of travel to the tropics. Issues to cover include

- Providing an adequate supply of currently used medications
- Identifying optimal sources of medical care in planned destinations (and obtaining adequate medical insurance to cover such care)
- Discussing potential legal restrictions on travel
- Providing education on avoiding food-, water-, and vector-borne disease
- Providing vaccination, chemoprophylaxis, and antimicrobial agents as appropriate reviewing the medical geography of the route and planned activities to identify any special risks

- Providing for adequate medical follow-up on return from travel

Prior to travel, those at risk of HIV infection should be screened for infection as part of the routine pretravel evaluation. Those known or found to be HIV infected should have their disease staged by CD4 count and viral load because the level of immunosuppression will influence the travel medical recommendations given. Therapy with HAART can complicate tropical travel.<sup>715</sup> For those already on HAART, concerns include

- The problem of appropriate clinical and laboratory monitoring—for those planning extended residence in places lacking appropriate clinical or laboratory services, it would be prudent to schedule two or three trips per year for medical follow-up to a country where such services are available
- Difficulties with compliance with complicated HAART regimens during the dislocations and changing daily schedules of travel
- The fact that approximately 50 countries currently restrict the entry of those infected with HIV, especially long-term visitors such as students and workers, despite compelling arguments against the utility and for the counterproductive nature of such policies

An unofficial listing of country requirements is available at <http://travel.state.gov/travel/HIVtestingregs.html>. Because possession of HAART medications may reveal the traveler's HIV infection, a potential solution is to remove or cover drug labels. Clearly, this is not without its own risks, which demand that careful records (medication names, dosages, frequencies, and physical appearance) be kept in more than one safe place by the traveler. Finally, there is the problem of untoward drug interactions with protease inhibitors. When initial HIV infection diagnosis and/or staging occurs during pretravel evaluation, the traveler may be newly recognized to fall into a group for whom HAART therapy is recommended. For those planning short-term travel, initiation of HAART just prior to departure is probably unwise due to the risk of developing significant side effects—many of which tend to be worse with initiation of therapy and some of which are intensified by stress—in the absence of close contact with a knowledgeable provider. For those in this situation who are planning long-term residence in the tropics, departure should probably be postponed until the traveler is stably on HAART therapy, unless close, timely follow-up can be achieved in the destination country. A critical variable, as ever in the rapidly changing field of HIV clinical care, is adequate, ongoing experience. Travel physicians without extensive, current experience in the care of those with HIV/AIDS should be in close consultative contact with physicians who possess this expertise: Today's verities rapidly become out of date. Textbooks of HIV care with frequent Web-based updates are also valuable resources.<sup>76,77</sup>

Sufficient quantities of currently used medications, along with replacement prescriptions, are essential. Patients should be counseled to seek medical attention promptly when ill. Although the current communication revolution allows a growing number of traveling patients to stay in close contact with their HIV and travel medicine physicians at home via e-mail, the prior identification of physicians with significant HIV experience in countries of planned travel is prudent. Obtaining medical insurance to cover such care is wise.

Another basic consideration, especially for those with advancing HIV-related disease, is the buying of trip cancellation and/or repatriation insurance.

Enteric pathogens are a major threat to the HIV-infected traveler to the tropics. In addition to the fact that many tropical travel-associated enteric bacterial infections are more severe in the presence of HIV coinfection, the achlorhydria that occurs in AIDS may markedly lower the amount of inoculum needed for the establishment of infection.<sup>566,567</sup> Precautions recommended for all travelers should be followed assiduously. Foods and beverages may be contaminated, particularly raw, unpeeled fruits and vegetables; raw or undercooked eggs; meats; seafood; tap water; ice; unpasteurized dairy products (beware of soft cheeses); and food purchased from street vendors.<sup>213</sup> Steaming hot foods, meat cooked until brown throughout, water brought to a boil for 1 minute, bottled (especially carbonated)

beverages, very hot beverages, beer and wine, and fruits and vegetables peeled by the traveler are generally safe.<sup>213</sup> In addition to preventing enteric disease, following these precautions will also lower the risk of infection with *T. gondii*. Treating water with iodine or chlorine may be done, preferably in conjunction with filtration, when boiling is not practical. Filtration of water, using reverse osmosis or sub 1 micron filters, is efficacious in removing *Cryptosporidia* from water.<sup>716</sup> All tap water should be avoided, even small amounts used for brushing teeth. Recreational water exposure also carries a risk. Obviously, fecally contaminated water should be avoided altogether. Swallowing water while swimming should be avoided.<sup>213</sup> Direct contact with soil and sand should be avoided in places where fecal contamination is likely; hands should be washed frequently. Antimicrobial prophylaxis for enteric pathogens is not routinely recommended for HIV-uninfected

**Table 133-1** Immunizations for HIV-Infected Adults Who Are Traveling to the Tropics

Vaccine	Recommendation	Comments
Routine immunizations*		
Tetanus–diphtheria	Boost every 10 yr	Recommended by USPHS–IDSA Recommended by ACIP, USPHS–IDSA Year-round infection in the tropics Southern Hemisphere: April through September; repeat annually
Pneumococcus	Use 23-valent polysaccharide vaccine; boost at 5 yr	
Influenza		
Hepatitis B	3 doses of Recombivax HB or Engerix B	
Measles†	Single dose of measles vaccine or MMR for susceptible persons who are not severely immunosuppressed; in the face of severe immunosuppression, consider immunoglobulin	
Standard travel immunizations		
Hepatitis A	Single dose 2 wk prior to travel; boost at 6–12 mo	Oral (live) vaccine is contraindicated and discouraged in close contacts Side effects lessened with polysaccharide vaccine; live oral vaccine is contraindicated
Poliomyelitis	Single dose of enhanced inactivated vaccine	
Typhoid	Single dose of polysaccharide vaccine at least 2 wk prior to travel; boost at 2 yr Alternately, two doses (separated by at least 1 mo) of inactivated vaccine; boost at 3 yr	
Yellow fever†		Contraindicated by the ACIP; recommended for those with asymptomatic HIV infection by WHO; considered for those with asymptomatic HIV infection who cannot avoid potential exposure, by USPHS, IDSA
Special travel immunizations		
Cholera	Two doses, at least 1 wk apart; boost at 6-mo intervals	Rarely indicated, given low risk of disease and limited effectiveness of vaccine; live vaccine contraindicated
Meningococcus	Single dose (A/C/Y/W-135)	
Plague	Three doses (one each at 0, 1, and 3–6 mo), with boost at 1 or 2 yr	Avoid giving HDCV given intradermally, given potentially weaker response
Rabies	See text	
Japanese encephalitis	Three doses, one each on days 0, 7, and 30; boost, based on antibody levels, at 1–3 yr	

\*Routine primary series of immunization for diphtheria–tetanus, MMR, and polio is assumed.

†Absolutely or relatively contraindicated in some circumstances.

travelers. For HIV-infected travelers, such prophylaxis may be considered, however, depending on the level of immunosuppression, the risk of infection, and the duration of travel.<sup>213</sup> Fluoroquinolones are probably the drugs of choice. All HIV-infected travelers should carry antimicrobials (with or without antimotility agents) for an empirical treatment course in case diarrhea develops. Ciprofloxacin 500 mg twice a day for 3 to 7 days is a reasonable choice. Alternatives such as TMP-SMX or azithromycin should be used for children and pregnant women. Medical attention should quickly be sought if empirical therapy fails, if shaking chills or hematochezia occur, or if dehydration develops.<sup>213</sup>

Contact with arthropod vectors should be reduced through the careful use of insect repellents, wearing clothes that cover the arms and legs when outdoors, sleeping in well-screened areas or under a bed net, and avoiding outdoor exposure between dusk and dawn (see Chapter 120). The threat of sandfly transmission of visceral leishmaniasis (see Chapter 94) deserves special mention and education.

Malarial chemoprophylaxis is essential, where indicated, for all travelers. The HIV protease inhibitors currently used for HAART have understudied interactions with a variety of drugs used for malaria prophylaxis and treatment. Based on current data, mefloquine, doxycycline, chloroquine, and malarone (atovaquone + proguanil) are likely to be safe and to retain efficacy for malaria prophylaxis. The provision of empiric, standby treatment doses (e.g., of malarone) seems prudent.

Recommendations for the immunization of HIV-seropositive travelers to the tropics are summarized in Table 133-1. Preparation for travel should include a careful review of routine vaccinations in addition to both routine and special travel vaccinations. Vaccine response rates, as measured by antibody titers, tend to decline with increasing HIV-related immunosuppression. This gives impetus, especially for "routine" vaccinations, to early identification of the need for vaccination. Essentially all live bacterial and viral vaccines are considered to be contraindicated in the presence of HIV infection,<sup>213</sup> including oral polio vaccine, oral typhoid vaccine (Ty21a), and BCG. The special cases of measles and yellow fever vaccines are considered in the "pathogen-centered" discussions earlier in the chapter and in Table 133-1.

The risk of acquisition of tuberculosis is much higher in most tropical countries than in the United States, although the risk of becoming infected during short-term travel is low. As noted previously, the ACIP and the USPHS-IDSA working group consider the administration of BCG to be contraindicated because of the risk of dissemination, although it is recommended by WHO for those with asymptomatic HIV infection in areas with a high prevalence of TB infection. All HIV-infected people should receive PPD testing. Follow-up testing after return from the tropics (or during travel or residence in the tropics, if extended) should be performed. With a positive PPD (>5 mm induration) or a known high-risk exposure, HIV-infected people with no evidence of active TB, or history of treatment for latent or active TB, should be treated for latent TB.<sup>213</sup> Whether primary chemoprophylaxis should be recommended for travel in areas with a high population prevalence of TB is unclear.

The endemic systemic fungi carry considerable risk for HIV-infected travelers. Where the environmental sources are known, the risk of infection may be reduced somewhat by

attempting to minimize exposure. Such measures include avoiding soil exposure, especially during the rainy season, in southern China and Southeast Asia (*P. marneffei*); avoiding exposure to disturbed soil and dust in lower Sonoran life zones of the Americas (*C. immitis*); and avoiding caves and soil and dust exposure in areas with heavy avian and bat excrement (*H. capsulatum*). Most often, the reservoirs are either unknown or too widespread to allow for avoidance. Primary prophylaxis with itraconazole (200 mg daily) may have merit for short-term prophylaxis during travel in areas with a high incidence of systemic fungal infection.<sup>340,717</sup>

Finally, it may be wise to avoid some areas of high potential risk by changing the planned travel itinerary or activities, especially for those people with advanced HIV disease. In this regard, it should be noted that many of the tropical infectious diseases of special concern here, such as yellow fever, have a fairly focal pattern of risk within endemic countries.

# Travel-Related Health Concerns Associated with Extremes of Environment

DAVID A. BOBAK  
PAUL S. AUERBACH

## INTRODUCTION

In addition to a variety of infectious diseases confronting travelers to tropical areas, there are other health concerns that can arise from exposure to the environment. Without adequate preventive measures, a traveler may develop a serious illness or exacerbation of an underlying medical problem. In this chapter, we address certain travel-related health disorders caused by extremes or changes in the environment.

## HEAT-RELATED ILLNESS

### Background

In most circumstances, humans are extremely tolerant of heat, an attribute most likely reflecting the common evolutionary origin of our species from tropical Africa. However, on exposure to excessively hot and humid conditions, unacclimated people or people with certain underlying medical problems can be especially prone to develop serious heat-related illnesses, such as heatstroke. Furthermore, despite dramatic improvements in cooling methods used for the treatment of heatstroke, there has been little real decrease in mortality or morbidity due to this illness in the past few decades.<sup>1</sup> For these reasons, understanding the basic principles of prevention, diagnosis, and management of heat-related illness is important for health-care providers who offer pretravel counsel or onsite care to travelers to tropical countries.

Health disturbances related to heat are conveniently, although somewhat arbitrarily, divided into minor disorders, such as prickly heat, heat cramps, heat edema, heat syncope, and heat exhaustion, and the much more severe disorder known as heatstroke. Heatstroke is further categorized into “classic” and so-called exertional forms based primarily on epidemiologic criteria.<sup>1-7</sup> The clinical descriptions of the common

heat disorders are discussed in this chapter as relatively discrete clinical entities, but in reality these distinctions are frequently blurred and heat-exposed patients may present with multiple or mixed syndromes.

## Thermoregulation

Core body temperature is the net result of a variety of internal and external factors, each working to increase or lower body temperature. This observation is clinically relevant; for example, the most important pathophysiologic defect underlying the development of the life-threatening disorder of heatstroke is the loss of the body's ability to maintain normal thermoregulation.<sup>1-3,7</sup> Humans have internal homeostatic mechanisms that normally act to preserve a preset equilibrium between heat production and heat loss. By this means, body temperature is maintained within a relatively narrow temperature range. Net heat production results from the heat absorbed from external sources and that generated from internal metabolic processes.

The major mechanisms of heat transfer in humans include radiation, conduction, convection, and evaporation.<sup>2,4,6</sup> Radiation is the process of heat transfer via electromagnetic waves. A person placed in an environment in which the air temperature is lower than the body temperature will lose heat predominantly by radiation. In contrast, a person placed in an environment in which the air temperature is much greater than the body's temperature will actually gain heat by the same process of radiation. In the process of conduction, heat is transferred directly from warmer to cooler objects by physical contact. In normal circumstances, only a small amount of heat loss from the body occurs by conduction. However, if a person is immersed in cool water, heat loss by conduction is markedly increased, a phenomenon that has therapeutic implications for the treatment of heatstroke. Convection is the loss of heat into the molecules of air and water vapor circulating around an object. In this way, heat is dissipated into moving, cooler air passing over a warmer object such as a person's body. As might be expected, the efficiency of heat loss by convection is dramatically influenced by both wind speed and air temperature.

Finally, heat is lost when a liquid is converted into a gas, a process known as evaporation. Evaporation is an extremely important mechanism for heat loss in humans, especially for people exposed to a high ambient temperature. When the ambient temperature exceeds 35°C (95°F), almost all of a person's heat loss occurs by evaporation. The efficiency of evaporation is influenced considerably by the level of ambient humidity. As humidity increases (particularly above 75%), the efficacy of evaporation decreases markedly. This is the reason why even a profusely sweating person will lose little heat under conditions of high ambient humidity.

## Predisposing Factors

Loss of normal thermoregulation is caused by a combination of several factors: excessive exogenous heat gain, increased endogenous heat production, decreased heat loss, or a combination of these.<sup>1-4,6</sup> Excessive exogenous heat gain typically occurs when a person enters an environment of high ambient temperature and high humidity. Endogenous heat production

can be increased by exertion, pharmacologic agents, or clinical syndromes such as febrile illnesses, seizures, and hyperthyroidism. In a cyclic fashion, endogenous heat production can increase basal metabolism and generate increased endogenous heat. Tricyclic antidepressants, amphetamines, cocaine, and phencyclidine are examples of drugs that can induce hyperthermia through an increase or dysregulation of muscular activity.<sup>7</sup> Sympathomimetic drugs can also cause hyperthermia, probably by altering hepatic metabolism.<sup>7</sup>

A variety of other factors can serve to impair the body's ability to dissipate heat.<sup>1-4,6</sup> Dehydration and volume depletion are important risk factors for hyperthermia. These factors cause decreased sweating and alter the compensatory cardiovascular responses normally triggered by hyperthermia. For these same reasons, people with significant cardiovascular disease are also at increased risk of heat-related illness. Because the major cooling mechanisms of the body use the cutaneous vascular system, abnormal regulation of blood flow can dramatically inhibit the efficacy of heat loss. Examples of conditions that result in circulatory inefficiency include congestive heart failure, atherosclerotic coronary vascular disease, and peripheral vascular disease, as well as ingestion of medications that may alter cardiovascular function (e.g., diuretics,  $\beta$ -blockers, and calcium channel blockers). In addition to being at greater risk of acquiring heat illness, patients with circulatory insufficiency are also at higher risk of developing heat stress-induced medical illnesses, such as myocardial infarction, congestive heart failure, cardiac dysrhythmias, and stroke.

Patients with significant abnormalities of the skin, such as scleroderma, or metabolic diseases, such as cystic fibrosis, have a defect in heat dispersion efficiency and are also at higher risk of developing heat-related illness.<sup>2,6,8</sup> Obese people have several factors that increase their risk of heat-related illness: ineffective heat dispersion because of increased insulation, a large surface area-to-mass ratio, and impaired cardiovascular conditioning. In addition, acute and chronic alcohol use are associated with an increased susceptibility to heat illness. The ingestion of alcohol impairs recognition of heat stress, inhibits normal compensatory behavioral responses, causes peripheral vascular dilation, and inhibits antidiuretic hormone.

Finally, it is important to recognize that infants and the elderly are particularly susceptible to heat-related illness. Normal thermal regulatory and sweating mechanisms are underdeveloped in neonates and infants. In addition, children have a larger surface area-to-mass ratio, sweat less, and have a higher metabolism than adults—all factors that can inhibit effective heat loss.<sup>5,9</sup> Many factors have been identified to explain the predisposition of the elderly to heat illness: relative cardiovascular inefficiency, reduced sweat production, lessened physical conditioning, a higher likelihood of underlying cardiovascular disease, and increased use of drugs that may interfere with cardiovascular or sweating responses to heat.

### Minor Heat-Related Disorders

**Prickly Heat.** Prickly heat, or heat rash, is a maculopapular, pruritic, and erythematous rash that most commonly appears over clothed areas of the body.<sup>6,10</sup> Prickly heat occurs when sweat pores are blocked, leading to inflammation of the sweat ducts. The predominant clinical feature of this condition is intense itching. Effective treatment involves exposing the

rash to cool, dry air and the administration of antihistamines. Prickly heat can frequently be prevented by wearing loose-fitting clothing. Complications of prolonged heat rash can include secondary cutaneous infections (most commonly with *Staphylococcus aureus*) or the development of chronic dermatitis.

**Heat Cramps.** Heat cramps are caused by involuntary and painful contraction of skeletal muscles.<sup>4,6,11-13</sup> The muscles most frequently affected are those that are most commonly used, such as the musculature of the shoulders, thighs, and calves. Heat cramps usually occur when physically unfit or heat-unacclimatized people exercise in a hot environment. Clinically, patients with this disorder generally present with acute and severe muscle pain. Importantly, the patient's temperature and other vital signs are usually normal. How heat cramps occur is not exactly known, but the pathophysiology likely involves disordered fluid and electrolyte balance at the level of the individual muscles. The risk of developing heat cramps appears to be increased in people who combine prolonged exercise in a hot environment with hypotonic fluid (e.g., water) replacement. In rare instances, a patient may exhibit evidence of heat- and exertion-induced rhabdomyolysis. With rhabdomyolysis, muscle pain is generally out of proportion to the other physical findings observed on physical examination. Laboratory investigation (e.g., urinalysis and muscle enzyme levels) is needed to clearly differentiate the serious disorder of heat-induced rhabdomyolysis from the benign disorder of heat cramps.

Heat cramps are generally benign and generally respond to massage, rest, and rehydration. For mild cases, treatment consists of massage and oral rehydration with a 0.1% or 0.2% saline solution or one of many commercially available electrolyte drinks. For severe cases, intravenous rehydration with normal saline solution can provide dramatic resolution of symptoms. When physical exertion in a hot environment is anticipated, maintaining adequate hydration will frequently prevent heat cramps. Fluid replacement with water alone appears to be satisfactory for mild to moderate exercise of short duration (30 minutes or less). With vigorous exercise for longer time periods, or in an extremely hot and humid setting, an appropriate electrolyte-containing solution should be used as fluid replacement.

**Heat Edema.** Heat edema is characterized by swelling and tightening of the hands and feet, usually within the first few days of exposure to a hot environment.<sup>6,13</sup> Unacclimatized or elderly patients are especially prone to this disorder. Not uncommonly, otherwise healthy travelers originating from a colder climate develop heat edema within a few days after arrival in a tropical area. The edema is usually mild; signs and symptoms of other systemic causes of edema are absent. Excessive orthostatic pooling of interstitial fluid in the extremities secondary to cutaneous vasodilation appears to be the major mechanism of heat edema formation. No treatment is usually necessary and the edema gradually responds within hours to days. Occasionally, however, edema may last for up to 4 to 6 weeks, and in these cases, leg elevation and support stockings may hasten resolution. Diuretics should not be used for the treatment of heat edema because they are ineffective and can actually predispose the patient to developing more serious heat-related disorders by causing dehydration.

**Heat Syncope.** Normally, hyperthermia induces shunting of blood to peripheral tissues to hasten cooling. In some

people, this physiologic response can produce a variant form of postural hypotension known as heat syncope.<sup>4,6</sup> As with heat edema, heat syncope most commonly occurs in unacclimatized people early after prolonged exposure to a hot environment. Most patients with heat syncope do not have true volume depletion. In patients presenting with the clinical syndrome of heat syncope, care should be taken to exclude other causes of syncope. For treatment, the patient should be placed supine, moved to a cool environment, and given rehydration fluids. Elastic long-legged support hose may assist in prophylaxis.

**Heat Exhaustion.** Heat exhaustion is an ill-defined and somewhat nonspecific heat-related syndrome.<sup>1,3,4,6,14,15</sup> Patients complain of any of a variety of symptoms, including headache, weakness, dizziness, malaise, lightheadedness, fatigue, myalgias, muscle cramping, nausea, and vomiting. The core body temperature is extremely variable and ranges from normal to 40°C (104°F). Clinical manifestations usually include orthostatic hypotension, tachypnea, tachycardia, and diaphoresis in addition to hyperthermia. Most important, though, the patient's mental status is normal. The pathophysiologic mechanisms of heat exhaustion are not well understood but are believed to be related to a moderate loss of electrolytes and water secondary to excessive sweating. Laboratory tests are not diagnostic, but there is usually evidence of hemoconcentration (elevated hematocrit) and dehydration [alterations in blood urea nitrogen (BUN), creatinine, sodium, and chloride]. Patients who have been able to partially rehydrate during heat exposure usually present with an isotonic pattern of volume depletion (normal serum sodium and chloride levels). In contrast, patients who did not hydrate prior to presentation usually develop a hypernatremic type of volume depletion. In mild cases of heat exhaustion, oral rehydration is usually satisfactory as treatment. However, if there is evidence of moderate to serious volume depletion, intravenous fluid replacement is necessary.

When evaluating a patient with presumed heat exhaustion, the clinician must consider the diagnosis of heatstroke, a much more serious condition that represents a true medical emergency. Most investigators agree that the presence of any significant alteration of mental status or the presence of severe hyperthermia (>40°C) in a heat-exposed patient warrants strong consideration of the diagnosis of heatstroke, regardless of other factors. Patients presenting without these two major factors most likely have heat exhaustion and should be treated with carefully monitored rehydration therapy and transferred to a cool environment. If there is any doubt as to the differential diagnosis between heat exhaustion and heatstroke, empirical treatment should be initiated for heatstroke because delay in the institution of the aggressive cooling measures may have serious or even fatal consequences for the patient.

**Heatstroke.** Heatstroke afflicts people in the temperate climates of the United States and Europe during heat waves, but it is a continual and significant cause of morbidity and mortality for people residing in hot climates.<sup>1-4,6,16-18</sup> For example, during the 1987 Haj, more than 2000 cases of heatstroke were reported and at least 1000 people died.<sup>19</sup> Even in the United States, more than 4000 cases are reported each summer.<sup>16-18,20-22</sup> Although heatstroke is traditionally divided into classic and exertional forms, a combination of the two types is most often seen. Classic heatstroke occurs principally during summer heat waves and is most likely to affect young children, the elderly, and patients with a debilitating disease.<sup>1,2,4,16-18</sup>

The pathophysiologic factors implicated in classic heatstroke include exposure to excessive ambient heat and humidity combined with an impaired ability for heat dissipation.<sup>2,4,6</sup> The typical victim of classic heatstroke is an elderly or debilitated person confined to a poorly ventilated room.<sup>16-18</sup> Dehydration, which limits heat dissipation, is also frequently present. All of the previously discussed risk factors for acquiring heat-related illness will also predispose a person to develop classic heatstroke.

Exertional heatstroke is caused by excessive heat production within skeletal muscles, triggered by exercising in a hot and humid environment. When muscles work at maximal intensity, much of the muscle energy is converted into heat, which is then transferred from the muscle to blood, thereby raising the core body temperature. Patients who suffer from exertional heatstroke usually do not have intrinsic metabolic defects of their skeletal muscles or any obvious abnormalities of thermoregulatory systems. As opposed to classic heatstroke, exertional heatstroke occurs sporadically and usually affects young, otherwise healthy people who engage in strenuous activity. Microarray gene expression analyses have been performed in Marines presenting with exertional heat injury, finding significant changes in expression of hundreds of gene products.<sup>23</sup> In this study, upregulated expression of known heat-shock responsive genes was observed as expected. However, there was altered expression of a large number of other gene products, including many belonging to interferon-inducible, nonspecific stress and apoptosis signaling pathways. These and similar studies suggest that exertional heat injury induces a very complex pattern of gene expression of cytokines, heat-shock proteins, stress response proteins, and regulators of cellular apoptosis.<sup>2,23</sup> People typically at risk for exertional heatstroke include military recruits, industrial workers, and athletes. Predisposing factors for exertional heatstroke include heavy or tight-fitting clothing, exposure to direct sunlight, dehydration, poor cardiovascular conditioning, and lack of acclimatization to heat.<sup>2-4,6</sup> Essentially all of these predisposing factors can be anticipated; therefore, most cases of exertional heatstroke should be preventable.

Although there are differences in the pathophysiology of the classic and exertional heatstroke syndromes, the clinical manifestations of both forms are very similar.<sup>1-4,6,10,14,15,20-22</sup> Most patients with heatstroke have extremely elevated core temperatures ( $\geq 40.5^{\circ}\text{C}$  or  $105^{\circ}\text{F}$ ). Altered mental status is nearly universal, and the presenting neurologic disturbances can range from confusion, lethargy, stupor, or coma to agitated states such as delirium or seizures.<sup>1-4,6,24,25</sup> Although severe central nervous system symptoms are generally present during heatstroke, patients who survive usually do not exhibit any serious neurologic sequelae. Patients with heatstroke also present with cardiovascular symptoms and signs, including tachycardia, hypotension, arrhythmias, and, occasionally, shock, myocardial ischemia, or pulmonary edema.<sup>1-4,6,26</sup> Pulmonary findings in heatstroke victims include tachypnea and in severe forms can include acute pulmonary edema, aspiration pneumonia, or adult respiratory distress syndrome. Additional clinical manifestations of heatstroke include oliguria, vomiting, diarrhea, hematuria, gastrointestinal bleeding, and disseminated intravascular coagulation. Cutaneous manifestations are variable. The skin can be hot and dry but may be moist and clammy. In addition, some patients may exhibit evidence of a hemorrhagic diathesis.

Heatstroke causes widespread damage to multiple organ systems; therefore, laboratory abnormalities may be diverse.<sup>1-4,6,26</sup> Leukocytosis and hemoconcentration are very common. Hematologic abnormalities are also frequently present and can include thrombocytopenia, prolonged prothrombin time, depressed fibrinogen level, and elevated fibrin split products.<sup>27,28</sup> Laboratory evidence of disseminated intravascular coagulation is more common in exertional than in classic heatstroke.<sup>2,3</sup> Bleeding problems related to coagulopathy can persist for up to 36 hours after onset of heatstroke. Abnormalities of renal function are relatively common in heatstroke and include oliguria, hematuria, myoglobinuria, proteinuria, and the presence of urinary casts. BUN and creatinine levels are usually elevated. Approximately one-third of patients with exertional heatstroke present with acute renal failure. Evaluation of military recruits developing acute renal failure in the setting of exertional heatstroke showed elevated levels of certain pressor hormones in the circulation (e.g., renin, aldosterone, and catecholamines) and nitric oxide metabolites, accompanied by a decrease in prostaglandin E<sub>2</sub>, a vasodilatory molecule.<sup>29</sup> Disturbances of liver function are also common in victims of heatstroke and include elevated bilirubin and transaminase levels. In addition, evidence of muscle damage includes elevation of serum creatinine phosphokinase and aldolase. Severe muscle injury can produce myoglobinuria and acute renal failure.

Multiple metabolic and electrolyte abnormalities are caused by heatstroke.<sup>1-4,6,26</sup> Early in the heatstroke syndrome, respiratory alkalosis is classically present. As the disease progresses, lactic acidosis may occur. In general, potassium levels are low early and high late in the course of the disease. Hypophosphatemia and hypoglycemia are relatively common in patients with exertional heat stroke. Elevated levels of inflammatory cytokines are frequently present and may well be a significant cause of the pathophysiology of the disease.<sup>2,23,30,31</sup> In some patients, electrocardiographic abnormalities are observed, including conduction disturbance and ST-T segment changes.<sup>32</sup> The differential diagnosis of heatstroke is broad and includes severe infection, sepsis, hyperthyroid storm, pheochromocytoma, anticholinergic poisoning, various toxicities, and the neuroleptic malignant syndrome.<sup>1,2,4,6,13</sup>

Heatstroke is a medical emergency and requires prompt and aggressive therapy.<sup>2,4-6,33,34</sup> Lowering the body temperature is the critical element in management. Antipyretic medications are ineffective because the pathogenesis of heatstroke involves thermal regulatory failure, not an alteration of the thermal set point, as seen in true fever. Immediate management in the field includes removing the patient's clothing, fanning the patient, bathing the patient's skin with cool water, or applying ice packs if available. The patient should be protected from sunlight and moved to a cool environment. Evacuation to a clinic or hospital should be performed as soon as possible. Rigorous physical cooling must occur as soon as the proper facilities are available. The traditionally recommended techniques for cooling heatstroke patients involved total body immersion in ice water or direct application of ice packs to the body. Both of these direct cooling techniques had the disadvantage of producing cutaneous vascular constriction, an effect that impedes the body's ability to effectively transfer heat. Despite these theoretical disadvantages, however, most series have reported ice water or cold water immersion as being extremely effective, especially for exertional

heatstroke.<sup>33,34</sup> An alternate technique for cooling that is also widely recommended relies primarily on evaporation rather than on conduction to facilitate heat loss. With this treatment, the patient is placed in the path of a cool water spray (approximately 15°C or 60°F) and warm air is then blown over the patient.<sup>2,6,35</sup> Familiarity with the technique and availability of the equipment vary widely, however, whereas facilities for cold water or ice water immersion are generally available. Regardless of the method of cooling employed, it is critical that the institution of cooling not be delayed and that once stabilized, the patient be transferred to a health care facility for further evaluation.

Irrespective of the technique used, the patient's core temperature should be carefully monitored during the cooling phase. Significant cooling usually occurs within 15 to 60 minutes and care must be taken not to overcool the patient. Induction of hypothermia has been reported with vigorous and lengthy cooling treatments. If dehydration is present, room temperature intravenous fluids should be given. This therapy is helpful in replacing volume and correcting electrolyte imbalances, and it may decrease the incidence of subsequent complications, such as renal failure or cardiovascular decompensation. After initial on-site treatment, heatstroke patients should be transferred to a clinic or hospital for further follow-up and management of potential complications, as detailed elsewhere.<sup>2,4,6</sup>

## ILLNESS ASSOCIATED WITH EXPOSURE TO THE SUN

### Background

Exposure to sunshine has certain benefits, such as promoting vitamin D synthesis. However, excess exposure to ultraviolet (UV) radiation associated with solar exposure can present a significant health risk as well.<sup>36</sup> The risk is directly related to the intensity, duration, and frequency of exposure to the sun. UV radiation is subdivided by wavelength into UVA, UVB, and UVC. UV radiation is essentially responsible for almost all sun-induced disorders. The time of day and season of the year are the most important factors in determining UV exposure. In addition, exposure from UV radiation can be amplified by reflection from snow, sand, or water. In order for UV radiation to induce biologic damage, it must first be absorbed. The specific light-absorbing molecules within the skin are termed chromophores and include melanin, keratin, porphyrin, and aromatic amino acids.<sup>36-40</sup> Absorption of light energy by a chromophore produces an excited state and can lead to liberation of heat or light, another chemical reaction, or generation of free radicals.

### Photosensitivity

There are two types of photosensitivity reactions: phototoxic and photoallergic.<sup>36-40</sup> Phototoxicity was originally thought to be an exaggerated sunburn response, primarily because both reactions are characterized by erythema, edema, hyperpigmentation, and desquamation of the affected areas. However, the UV spectrum patterns for these reactions are different: Photosensitivity reactions are almost always due to UVA exposure, whereas sunburn is due to excessive exposure to UVB.<sup>36,37,41</sup> Phototoxicity is classically seen with sun exposure following the ingestion of certain medications (Box 134-1). The usual clinical course

**Box 134-1 Medications Commonly Associated with Photosensitivity Skin Reactions****Phototoxicity Reactions**

Angiotensin-converting enzyme inhibitors  
 Amiodarone  
 $\beta$ -blockers

Data from references 36–46.

involves a burning sensation of the skin following exposure to the sun, which rapidly progresses to erythema, edema, and, in some cases, vesiculation. Changes become maximal within 2 to 6 hours after sun exposure and gradually resolve over 2 to 4 days. In certain cases, however, a delayed phototoxicity response may occur in which symptoms peak at approximately 48 hours after exposure. Symptomatic treatment is usually sufficient. A small number of patients may continue to experience phototoxic sun reactions even after the discontinuance of all suspected photosensitizers. Skin exposure to certain plant extracts can also be associated with a form of contact dermatitis.<sup>42</sup> In addition, lime juice, in particular, can cause a form of phytophotodermatitis characterized by erythema, pruritus, and/or blistering, an effect that is caused by endogenous furanocoumarins found in the juice.<sup>43–45</sup>

Photoallergy differs from phototoxic reactions in terms of both symptoms and pathophysiology.<sup>36,37,41</sup> The clinical

manifestations of photoallergy are usually of two types: the immediate development of urticaria or the delayed appearance of a papular, eczematous rash. These two syndromes reflect the primary pathophysiology of either antibody-dependent or cell-mediated immune responses that are involved in the respective syndromes. Overall, photoallergic reactions appear to be much less common than phototoxic reactions. Commonly implicated drugs are listed in Box 134-1. In addition to medications, many chemicals and fragrances found in common skin lotions, creams, and sunscreens are potential photoallergens.

**Sunburn**

Sunburn is an acute inflammatory reaction of the skin secondary to excessive exposure to UV radiation.<sup>36,41</sup> There is a marked individual variation in sunburn response rate to a given amount of sunlight exposure. For example, dark-skinned people have a higher resistance to sunburn. However, such people are more susceptible to sunburn reactions than is generally believed. The pathogenesis of sunburn is believed to be secondary to UV radiation–induced release of inflammatory mediators from mast cells and keratinocytes. Although prostaglandins are probably the most important of these mediators, histamine, serotonin, kinins, lysosomal enzymes, and oxygen free radicals have all been measured during the inflammatory phase of an acute sunburn reaction. The immediate response is erythema, which fades within 30 minutes of acute exposure. This reaction is followed by a latent period of 4 to 6 hours, after which the classic signs of warmth, tenderness, and edema occur. In very severe cases, fever, chills, nausea, and even delirium may be present. Scaling and desquamation usually occur in 3 to 7 days.

Treatment involves administration of cool topical soaks, nonsteroidal anti-inflammatory drugs, and avoidance of further sun exposure. Local anesthetic agents are frequently self-administered by patients. Because the cutaneous use of the “caine” type of local anesthetic can be associated with development of allergy, the routine use of these topical medications is not recommended. Some authors have reported success in using topical steroids, but others have found them to be of minimal benefit. In severe cases with systemic symptoms, a short, rapid tapering course of oral prednisone can be helpful in alleviating symptoms.<sup>36,46</sup>

**Solar Urticaria and Pruritus**

Occasionally, patients with excessive sun exposure may report the rapid onset of a pruritic, hivelike rash, a condition that has been loosely described as solar urticaria.<sup>47</sup> The exact pathogenesis of this disorder is not understood, although evidence implicates an IgE-mediated immediate type of hypersensitivity reaction. Symptomatic relief has been successfully achieved with antihistamine therapy. Another relatively uncommon manifestation of excessive sun exposure is a syndrome known as solar pruritus or brachioradial pruritus.<sup>48–50</sup> This condition is observed mostly in light-skinned people residing in tropical areas. The exact cause of this syndrome is also unknown. However, chronic sun exposure is a universal historical feature. Clinical presentation typically consists of a few weeks of intense pruritus, generally localized to the upper areas of the arms, shoulders, and upper back. In some patients, the pruritus is limited to the external aspect of the skin areas surrounding the

elbow, hence the term *brachioradial pruritus*. Other physical findings are usually absent. Treatment is limited to avoiding further sun exposure. The administration of capsaicin cream to the affected areas has proved beneficial in a few cases.<sup>49,51</sup>

### Polymorphous Light Eruption

An interesting and somewhat unusual cutaneous response to sun exposure is a condition known as polymorphous light eruption (PMLE).<sup>36,52,53</sup> The pathogenesis seems to be similar to that for a photoallergic reaction but no exogenous photoallergen is identifiable. Certain investigators have proposed an endogenous form of photoallergic reaction as being causative in PMLE. The incidence of PMLE appears to be equal in all races and it occurs without regard for skin pigmentation. The initial onset of disease usually occurs during childhood. Recurrence of pruritic, inflammatory skin eruptions in the area of sun-exposed skin is noted through young adulthood. The exact clinical presentation is extremely variable; skin findings range from papules, plaques, or nodules to frank eczema. Exacerbations tend to occur during the initial sun exposures of the year (i.e., spring) and tend to decrease as the year progresses. The differential diagnosis includes photosensitivity, photoallergy, porphyria, solar urticaria, and lupus erythematosus. Photo patch testing can provide evidence for the diagnosis of PMLE. Treatment is primarily symptomatic and involves avoidance of sun exposure, use of sunscreens, and therapy with oral antihistamines and topical steroids. In moderately severe cases, some success has been reported with the use of topical antioxidants or systemic steroids or other immunomodulating drugs.<sup>53</sup> In severe cases, 311 nm UVB or UVA1 phototherapy has also been used.<sup>53</sup>

### Sun-Induced Exacerbation of Systemic Diseases

In addition to primary sun-induced cutaneous damage or disease, excessive sun exposure can also exacerbate underlying diseases, such as porphyria and lupus erythematosus.<sup>36</sup> Sun sensitivity is especially prominent in four types of porphyria: erythropoietic porphyria, erythropoietic protoporphyria, protoporphyria cutanea tarda, and toxic porphyria. Cutaneous reactions secondary to sun exposure and photosensitivity are very common in patients with lupus erythematosus. Patients with discoid lupus erythematosus tend to have more sun-related skin problems than those with systemic lupus erythematosus. Rigorous avoidance of excessive sun exposure is critical to maintenance of remission in these groups of patients, especially those with a history of sun-induced exacerbations. Treatment protocols for flares of porphyria and lupus are summarized elsewhere. Other chronic skin disorders that have been reported to be aggravated by excessive sun exposure include dermatomyositis, psoriasis, and atopic eczema.

### Photokeratoconjunctivitis

UV radiation from excessive sun exposure can lead to certain ocular disorders.<sup>54,55</sup> People in bright sunlight and surrounded by the sea, sand, or snow can develop photokeratoconjunctivitis. The clinical presentation of this syndrome usually involves a latent period of several hours, followed by the subacute onset of a foreign body type of sensation (photophobia, tearing, blepharospasm, and pain) in the eyes.

Physical findings may be minimal and are typically limited to conjunctivitis and chemosis. Therapy involves oral analgesics, topical antibiotics, and topical mydriatics or cycloplegics. People in environmental settings at risk of photokeratoconjunctivitis are also at risk of development of another syndrome known as solar retinopathy. Patients with this sun-induced ocular reaction present with acute loss of visual acuity, development of a central scotoma, and macular edema. No specific form of therapy has proved beneficial, although visual recovery is the general rule in this condition. A rare patient, particularly one with significant carotid artery stenosis, may develop retinal ischemia with some amount of residual vision loss.

### Long-Term Effects of Excessive Sunlight Exposure

In addition to acute sun-induced diseases, there are two important adverse effects caused by chronic exposure to the sun. The development of dry, nodular, wrinkled, and telangiectatic skin in response to chronic sun exposure is known as photoaging or dermatoheliosis.<sup>36,56</sup> Histologically, photoaging is characterized by the development of abnormal keratinocytes, epidermal hypertrophy, and abnormalities of the sebaceous glands and dermal matrix. These abnormalities, along with dermal thickening, result in cutaneous changes consisting of deep wrinkles, accentuated skin furrows, and mottled pigmentation. A more serious risk of chronic sun exposure is the development of a cutaneous malignancy. There is a direct correlation between the amount of UV skin exposure and the risk of development of squamous cell and basal cell carcinomas.<sup>36,56</sup> There also appears to be a risk, although somewhat less clear-cut, between a history of sun exposure and the development of malignant melanoma.<sup>36,56,57</sup>

Avoidance of sun exposure and application of appropriate photoprotective agents are two key preventive factors that can decrease the incidence and severity of sun-induced disorders. Regarding the risk of cutaneous sun-induced disorders, skin pigmentation is an important prognostic factor. The incidence of most sun-induced diseases is much less in dark-pigmented people compared to light-pigmented people. However, prediction of sun sensitivity solely on the basis of degree of skin pigmentation alone is inadequate, especially among light-skinned people. Sunburning and tanning abilities are important independent prognostic factors as well. Fitzpatrick<sup>58</sup> described classification of skin into different types based on a person's history of sun sensitivity, ranging from type I (lightest pigmentation, always burns, never tans) to type VI (darkest skin pigmentation, never burns). This system has proved helpful in assessing the risk of sun-induced skin injuries in an individual patient. Assessment of a traveler's skin type is helpful in giving pretravel counsel related to sun-induced disorders. As with most environmental exposures (e.g., heat, cold, and altitude), acclimatization is also relevant in the instance of cutaneous photoprotection. Gradual low-level natural or artificial UV exposure appears to render most people less sensitive to sun-induced cutaneous disorders.

The simplest means of sun protection is to avoid exposure to sunlight between the hours of 11 AM and 3 PM. Hats, light clothing, and cutaneous sunscreens are photoprotective agents for outdoor exposure. A variety of chemical sunscreens are commercially available. A formulation with a sun protection factor (SPF) of 15 is generally recommended.<sup>36</sup> Sunscreens with SPF factors higher than 15 provide little additional benefit. Frequent and liberal reapplication of sunscreen is the key to effective photoprotection. Of note, most of the chemical

sunscreens have been reported to directly or indirectly cause one or more of the sun-related cutaneous reactions discussed in this chapter. Therefore, pretravel testing with a minute amount of sunscreen on a small area of skin can be helpful in avoiding disturbing chemical hypersensitivity.

### ILLNESS CAUSED BY ATMOSPHERIC POLLUTION

Essentially all travelers entering tropical countries will spend at least some time in a medium or large city. Most of the largest metropolitan areas in the world are located in underdeveloped or developing countries (Table 134-1).<sup>59,60</sup> Because air pollution laws and regulations in most developing countries are generally lax, travel-associated morbidity secondary to exposure to atmospheric pollution is a real concern for most travelers to such cities. Health hazards due to atmospheric pollution thus represent one category of medical problems shared by industrialized and developing nations.

Fossil fuel combustion and industries produce photochemical smog, carbon dioxide, carbon monoxide, suspended particulates, acid aerosols, and a variety of toxic pollutants, including lead, other heavy metals, and trace organics.<sup>61-66</sup> These agents have been associated with a variety of health problems in healthy adults as well as in patients with underlying cardiopulmonary problems, and they are associated with increased risk of morbidity and mortality among exposed populations (Table 134-2).<sup>61-83</sup> Cities with particularly notorious

**Table 134-2** Medically Important Atmospheric Pollutants

Pollutant	Populations at Risk	Range of Health Effects
Particulates	Healthy adults and children Patients with asthma, COPD, CLD, CHD	Increased respiratory symptoms Impaired lung function Increased airway reactivity/inflammation Increased respiratory illnesses Increased mortality in CHD, CLD patients
Tropospheric ozone	Healthy adults and children Outdoor workers Athletes Patients with asthma, COPD	Increased respiratory symptoms Impaired lung function Decreased exercise capacity Increased airway reactivity/inflammation Increased hospitalizations Effects worsened in combination with acid aerosols and particulates
Sulfur dioxide	Healthy adults and children Patients with asthma, COPD	Increased respiratory symptoms Impaired lung function Increased hospitalizations Increased respiratory infections
Nitrogen dioxide	Healthy adults and children Patients with asthma, COPD	Increased respiratory symptoms Impaired lung function Increased airway reactivity Increased respiratory infections
Carbon monoxide	Healthy adults and children Patients with IHD	Decreased exercise capacity Increased ischemic episodes and mortality in IHD patients
Lead, heavy metals	Healthy adults and children	Altered neurologic function Altered behavioral function Hematologic toxicity Increased incidence of hypertension Highest risk in countries allowing leaded gasoline
Acid aerosols	Healthy adults and children Patients with asthma, CLD	Increased respiratory symptoms Impaired lung function Impaired mucociliary clearance

CHD, chronic heart disease (all types); CLD, chronic lung disease (all types); COPD, chronic obstructive pulmonary disease; IHD, ischemic heart disease. Data from references 61-63, 71-75.

levels of air pollutants include Mexico City, cities along the Pacific basin of the Americas (e.g., Los Angeles), many cities within eastern Europe, Beijing, and most large cities in Asia. In many low-lying cities, temperature inversions can exacerbate the effects of air pollution. In addition, natural sources of particulates, such as sandstorms, can combine with extreme heat and artificial contaminants to cause increased respiratory health risks in many areas of North Africa and the Middle East.

Components of photochemical smog include sulfur dioxide, ozone, and nitrogen oxide. Exposure of people to elevated levels of sulfur dioxide in the atmosphere is associated with a measurable decrease in pulmonary function. As sulfur dioxide levels increase, exacerbation of disease in patients with underlying pulmonary disease is frequently seen. Patients with asthma and chronic obstructive pulmonary disease (COPD) appear to be particularly at risk of symptomatic flare secondary to high levels of sulfur dioxide and particulates. Ozone is another important component of photochemical smog. Elevated levels of ozone cause chest discomfort and eye irritation in normal adults and children. With high levels of tropospheric ozone, pulmonary dysfunction, bronchospasm, and inflammatory pulmonary exudates can be noted, even in otherwise healthy people. The third major component of photochemical smog is nitrogen oxide. This pollutant likely causes fewer acute or serious illnesses than the other agents, but at higher levels it has been associated with the induction of bronchospasm, decreased pulmonary function, and increased respiratory infection, primarily in patients with asthma or COPD. In cities with congested freeways and aging, poorly repaired automobiles, exposure to significant levels of carbon monoxide is a continual concern. In people with chronic exposure to low or medium levels of carbon monoxide, elevated carboxyhemoglobin levels, impaired cognition, and other symptoms of carbon monoxide toxicity may be observed. The diagnosis and treatment of carbon monoxide toxicity are summarized elsewhere.<sup>76,77</sup>

People who must go outdoors during peak episodes of atmospheric pollution should minimize the time of exposure, avoid exercise, and consider wearing particle-filtering masks. For patients with asthma or COPD, prophylactic treatment with oral antihistamines and aerosolized ipratropium bromide may be helpful. Finally, the risk of exposure to environmental allergens should always be considered when traveling, especially if the traveler has a history of atopic disease, asthma, or COPD.

## HIGH-ALTITUDE ILLNESS

### Background

The term *high-altitude illness* usually invokes images of technical mountaineering performed under arctic-like conditions. However, exposure to high altitude occurs in large numbers of travelers visiting tropical or subtropical countries every year. For example, trekking to the Mt. Everest base camp (5366 m/17,600 ft) or to the summit of Mt. Kilimanjaro in Africa (5891 m/19,321 ft) is a common tourist activity. This section provides an overview of some of the more common medical illnesses associated with travel to high altitude. For detailed discussions of the epidemiology, physiology, and pathophysiology of medical complications of high-altitude exposure, the reader is directed to recent journal reviews and book chapters.<sup>55,84–95</sup>

## Pathophysiology

Much of the understanding of the pathophysiology of altitude-related illnesses has come from the experiences of mountain climbers and high-altitude balloonists.<sup>96,97</sup> In addition, more recent use of high-altitude field testing and research stations has dramatically improved our understanding of the pathogenesis, presentation, and treatment of many altitude-related diseases. The unifying finding from almost all of these venues is that hypoxia represents the primary environmental stress responsible for the pathophysiology of most altitude-related illness.

At sea level, the partial pressure of oxygen is approximately 149 Torr (1 Torr = a unit of pressure sufficient to support a 1-mm column of mercury at 0°C) and results in a partial pressure of alveolar oxygen (PaO<sub>2</sub>) of approximately 100 Torr. Because the percentage of oxygen in the atmosphere is constant at 21%, the decreased barometric pressure at high altitude results in a decreased atmospheric partial pressure of oxygen. At an altitude of 4572 m (15,000 ft), the partial pressure of inspired oxygen decreases to approximately 80 Torr, which results in PaO<sub>2</sub> of approximately 43 Torr. *High altitude* is generally defined as an altitude higher than 2500 m (approximately 8200 ft), *very high altitude* as 3500 to 5500 m (approximately 11,500 to 18,000 ft), and *extreme altitude* as higher than 5500 m (approximately 18,000 ft; Table 134-3).<sup>55,89–95</sup> Mild forms of altitude sickness are relatively common at high altitude. Acclimatization is required to avoid medical complications when ascending to very high altitude. Serious medical problems are commonly associated with ascent to extreme altitude, even with appropriate periods of prior acclimatization.

**Table 134-3 Association of Symptoms with High-Altitude Exposure**

M	FT	Comments
2500	8,200	High altitude is 2500–3500 m; mild acute mountain sickness is common
3000	9,840	
3500	11,480	Very high altitude is 3500–5500 m; moderate altitude-related illness is frequent; serious problems commonly occur in unacclimatized people
4000	13,120	
4500	14,760	Mt. Everest base camp is 5366 m (17,600 ft)
5000	16,400	
5500	18,040	Extreme altitude is greater than 5500 m; altitude-related illness is universal, even in acclimatized people; a significant risk of serious medical problems is associated with extended stays at extreme altitude
6000	19,680	Mt. Kilimanjaro is 5891 m (19,321 ft)
6500	21,320	
7000	22,960	
7500	24,600	
8000	26,240	
8500	27,880	
8850	29,028	Altitude of Mount Everest

## Acute Mountain Sickness

Acute mountain sickness (AMS) is the most benign form of altitude-related illness.<sup>55,84–89,91–93,98</sup> This syndrome affects thousands of travelers and trekkers each year as they ascend to altitudes higher than 2500 m. Symptoms include headache, anorexia, nausea, vomiting, sleep disturbance, lethargy, and dyspnea on exertion. Symptoms most commonly occur when people undergo rapid ascent to altitudes higher than 2500 m. The severity of symptoms in AMS is increased by physical exertion, higher attained altitude, and more rapid ascent. The susceptibility to AMS varies dramatically among people and is often difficult to predict.<sup>99–101</sup> No consistent correlation has been found between the likelihood or severity of AMS and such factors as age, level of physical fitness, or sex. One report suggests that younger, less physically fit people living at low altitude had a higher risk of developing AMS.<sup>102</sup> Another study indicated that obese men exhibited higher AMS scores than nonobese men when subjected to a simulated ascent to 3658 m.<sup>103</sup> One factor that appears to be strongly associated with an increased risk of AMS is a previous history of altitude-related illness, especially when such people perform a rapid ascent.<sup>91–93</sup> For most people, the development of AMS is not associated with serious complications or sequelae. A minority of patients, however, can progress from the relatively benign syndrome of AMS to more serious illnesses, such as high-altitude pulmonary edema or high-altitude cerebral edema.

In most people, acclimatization to a certain altitude occurs over 2 or 3 days, after which symptoms of AMS usually decrease markedly.<sup>55,84–89,91–93,98</sup> For a mild case of AMS,

rest and acclimatization to the presently held altitude are frequently all that is needed. More troublesome symptoms can be relieved by treatment with a variety of drugs. In particular, administration of acetazolamide reduces the symptoms of AMS and improves pulmonary gas exchange and function (Table 134-4).<sup>55,84–89,91–93,98</sup> Acetazolamide therapy does not appear to interfere with the process of acclimatization. In patients with a previous history of AMS, acetazolamide therapy can reduce the severity of AMS if it is initiated immediately prior to ascent. Recommended dosing for acetazolamide varies by authors and ranges from 250 mg at evening to 250 mg every 8 hours.<sup>55,84,91–93</sup> We generally recommend 125 to 250 mg twice a day, depending on severity of symptoms and efficacy of response. Most authors recommend that acetazolamide be used for only a few days to facilitate acclimatization. Dexamethasone therapy also lessens the symptoms of AMS, especially in people who rapidly ascend to high altitudes.<sup>55,84–89,91–93,98,104</sup> Although dexamethasone is as good as or better than acetazolamide at relieving many of the symptoms of AMS, it has no measurable beneficial effect on pulmonary function. Therefore, most authors do not routinely recommend dexamethasone for either prophylaxis or as first-line therapy for the treatment of AMS.<sup>91–93</sup> In more severe cases of AMS, the combination of acetazolamide with dexamethasone should be considered, especially when descent is not an option.<sup>55,85,91–93,105</sup> Because acetazolamide is a sulfonamide, there has been general reluctance to prescribe this medication for a patient who gives a history of allergy to sulfonamide antibiotics. Strom and colleagues retrospectively analyzed a large general practice patient database in the United Kingdom and found that history of an allergy to penicillin

**Table 134-4** Treatment Guidelines for Serious Forms of High-Altitude Illness

Syndrome	Treatment	Comments
Acute mountain sickness (AMS)	Discontinue ascent Increase fluids Acetaminophen prn Acetazolamide 250 mg q8–12h or Dexamethasone 4 mg q6h If severe: supplemental O <sub>2</sub> and acetazolamide 500 mg q8h and dexamethasone 4–8 mg q6h	If prophylaxis is indicated More gradual ascent Acetazolamide 250 mg qhs or q12h (start day before ascent and continue for 3–5 days) or Dexamethasone 2–4 mg q6h (start day before ascent and continue for 3–5 days) Nifedipine not effective as prophylaxis for AMS; theophylline may be beneficial Nifedipine is also effective as a prophylactic agent Inhaled NO or beta-agonists (e.g., salmeterol) or sildenafil may be beneficial for prophylaxis or treatment based on small studies Dexamethasone does not benefit pulmonary function
High-altitude pulmonary edema	Discontinue ascent Bed rest Supplemental O <sub>2</sub> If moderate to severe: above and furosemide (titrated prn) and morphine (titrated prn) and nifedipine (10 mg sl, then 20 mg PO q6h or 30 mg SR PO q12h) and immediate descent or hyperbaric therapy if unable to descend	
High-altitude cerebral edema	Immediate descent and evacuation if possible or hyperbaric therapy if descent is not possible Supplemental O <sub>2</sub> Dexamethasone 4–8 mg q4h	

sl, sublingual; SR, sustained release.

Data from references 55, 84–89, 91–95, 104, 109, 124, 125, 130, 131, 136, 137.

was actually associated with a greater risk of allergy with administration of acetazolamide than was a history of an allergy to a sulfonamide antibiotic.<sup>106</sup> The authors concluded that an allergic history to “sulfa” drugs incurred only a small risk for developing an allergic reaction in response to acetazolamide. If there is no history of anaphylaxis and there is a strong medical need for use of acetazolamide, a small test dose of acetazolamide should still be carefully tried prior to travel before prescribing a full prophylactic or treatment regimen. Even then, acetazolamide use should be considered only when no other viable options (i.e., descent) are available.

Effective alternative agents for AMS are as yet unproven, although some preliminary studies are encouraging. Although spironolactone has been advised as a prophylactic agent, experience with this agent is limited and its routine use cannot be recommended at this time. Agents such as furosemide and nifedipine have been used successfully to treat patients with high-altitude pulmonary edema. However, there is no evidence that therapy with either of these agents is beneficial in the treatment or prophylaxis of AMS. Ginkgo biloba has been promoted as an effective and healthy alternative to acetazolamide for the prophylaxis of AMS. However, randomized, double-blind, placebo-controlled study of nonnative trekkers in Nepal found ginkgo ineffective in reducing either the severity or the incidence of AMS. In contrast, acetazolamide at 250 mg twice a day was very effective and displayed few adverse effects.<sup>107</sup> In a few small studies, prophylactic use of theophylline has been shown to have some efficacy in decreasing the severity or duration of AMS.<sup>108,109</sup>

A nonpharmacologic treatment for AMS involves use of a portable pressurization chamber.<sup>110</sup> Initial uncontrolled studies demonstrated that use of this apparatus in patients with AMS was associated with rapid and marked relief of symptoms.<sup>111,112</sup> Recent controlled studies indicate that there is indeed a greater short-term relief of symptoms (within 1 or 2 hours) using this apparatus.<sup>113–116</sup> However, there was no decrease in symptoms noted at later time points for patients treated with the pressurization apparatus compared with control patients placed in the apparatus but maintained at ambient atmospheric pressure. Evidence suggests that portable pressurization chamber treatment may slightly delay the onset of AMS but does not prevent AMS or decrease the severity of symptoms.<sup>113–117</sup> Use of portable pressurization devices should never substitute for descent when feasible. An empiric trial of use can be justified in the patient with a serious form of altitude illness who is unable to descend because of medical or logistical issues. Further studies are needed to elucidate the specific indications and potential benefits of the current, newer models of portable pressurization chambers.

It must be emphasized that the best and most effective therapy for AMS, as for all forms of altitude-induced illness, is descent to a sufficiently lower altitude.<sup>55,84,85,89,91–93,98</sup> In patients with moderate to severe symptoms of AMS, descent in combination with drug therapy as outlined previously should always be seriously considered. In addition, any symptoms that suggest the development of more serious complications, such as high-altitude pulmonary edema or high-altitude cerebral edema, mandate an attempt at descent. Prevention is often the best form of therapy. A slow and gradual ascent is probably the best way to prevent or at least reduce the severity of symptoms associated with AMS. Relevant to this point,

travelers are often at the mercy of schedules that may lack sufficient time allocation for gradual ascent. In these instances, travelers are encouraged to seek the guidance of a travel medicine advisor to obtain appropriate counsel as to the symptoms and treatment of AMS.

## High-Altitude Pulmonary Edema

High-altitude pulmonary edema (HAPE) is a potentially life-threatening condition that typically occurs in young, otherwise healthy people after rapid ascent to an altitude of 2500 m or higher.<sup>55,84–88,91–95</sup> Some individuals, however, can develop HAPE at moderate altitude (<2400 m). This appears to be more common than generally appreciated.<sup>118</sup> Symptoms of HAPE usually develop within 1 to 3 days following ascent and consist of orthopnea, dyspnea, and a cough productive of frothy, pink sputum. Patients with HAPE usually present with cyanosis, tachypnea, tachycardia, and rales. Development of HAPE appears to be more common in young males and has been associated with pre-existing lower respiratory tract infection, cold weather, history of previous episodes, and vigorous physical activity. The pathophysiology of HAPE most likely represents a variant of noncardiac pulmonary edema.<sup>90–95,119–125</sup> Pulmonary artery hypertension in the setting of normal pulmonary capillary wedge pressure is the characteristic finding. Most of these findings appear to be due to an excessive pulmonary vascular vasoconstrictive response to hypoxia. Earlier evidence indicated a prominent inflammatory component to HAPE, but this reaction may be coincidental rather than causal. Most current information regarding the pathophysiology of HAPE supports alteration of cardiopulmonary circulatory regulatory pathways, acid–base function, endothelial cell function, and vasoregulatory factors such as nitric oxide, atrial natriuretic peptide, and the renin–angiotensin system.<sup>90–95,119–125</sup> Further evidence indicates that genetic polymorphisms in some of these pathways may predispose certain individuals to HAPE.<sup>126–129</sup>

The mainstays of treatment of HAPE include immediate descent and oxygen therapy.<sup>55,84–86,88,90</sup> Certain drugs useful in other forms of pulmonary edema (e.g., furosemide and morphine) are also helpful in the treatment of HAPE. Acetazolamide, nifedipine, inhaled nitric oxide, salmeterol, and sildenafil have all been shown in clinical studies to improve both clinical symptoms and oxygenation defects associated with HAPE (see Table 134-4).<sup>55,84–86,88,91–95,124,125,130,131</sup> The reader is referred to detailed reviews and studies regarding specific treatment options for this disorder.<sup>91–95,124,125</sup>

## High-Altitude Headache

The hypoxia associated with ascent to high altitude can also cause a variety of neurologic problems. High-altitude headache is extremely common and usually seen in combination with other symptoms associated with AMS.<sup>91–93,132–134</sup> High-altitude headache tends to be more severe in patients who are younger, female, and have a high frequency of headaches at their baseline altitude of residence. In addition to the treatment for AMS, as outlined previously, placebo-control studies have indicated that treatment with aspirin or ibuprofen is highly effective for high-altitude headache.<sup>133,134</sup> Mild cognitive defects have been noted in conjunction with

AMS. Most of the changes appear to be mild and resolve after descent and symptomatic recovery from AMS.

### High-Altitude Cerebral Edema

The most serious neurologic problem associated with altitude is high-altitude cerebral edema (HACE).<sup>55,91–93,135–137</sup> This condition was formerly believed to occur only during ascent to extreme altitudes. However, HACE has been occasionally reported at modest altitudes, so travelers at risk should be familiar with the symptoms and clinical course of this syndrome. Initially, symptoms of HACE closely resemble those of AMS. With HACE, there is a relatively rapid progression of neurologic and cognitive defects, including severe malaise, weakness, dizziness, impaired memory, altered judgment, excessive drowsiness, visual disturbances, and hallucinations. Clinical signs suggestive of HACE include disorientation, somnolence, obtundation, paralysis, ataxia, and seizures. Retinal hemorrhages are not uncommon. A variety of pathophysiologic disturbances have been described for HACE: high brain capillary pressure with edema and vascular leakage, osmotic cell swelling, focal ischemia, and angiogenesis.<sup>55,91–93,135–139</sup> Cerebral pathologic changes noted on autopsy from patients with HACE include petechial hemorrhage, thrombosis, and gross edema.

Occasionally, clinical differentiation between moderately severe AMS and full-blown HACE is difficult. If there is any question of the presence of HACE, an attempt at immediate descent is mandatory. The presence of neurologic abnormalities, such as ataxia, obtundation, excessive somnolence, or confusion, should raise strong concern that the patient is suffering from HACE. In addition to rapid and immediate evacuation to a lower altitude, adjunctive therapies with oxygen and dexamethasone are known to be helpful and potentially lifesaving in this syndrome (see Table 134-4).<sup>55,91–93</sup>

### High-Altitude Retinopathy

Heavy physical exertion and a rapid ascent to very high altitude predispose the patient to develop high-altitude retinal hemorrhage.<sup>140–142</sup> The reported incidence of this syndrome is approximately 5% at 14,000 ft, 50% at 17,000 ft, and 100% at 21,000 ft. High-altitude retinal hemorrhage is generally asymptomatic, although macular visual field defects occasionally occur. Clinical findings include flame-shaped retinal hemorrhages, cotton wool exudates, and vitreous hemorrhages. Resolution is usually spontaneous with minimal sequelae following descent to a lower altitude, and most physical findings resolve within a few weeks. Although high-altitude retinal hemorrhage is not considered a serious problem, it is frequently associated with the presence of HACE or HAPE. The development of this form of retinopathy, therefore, must be an indication to carefully monitor the patient for further development of more serious altitude-related illnesses. Certain pre-existing ocular problems may also be exacerbated by ascent to high altitude. For more serious conditions, consultation with an ophthalmologist may be warranted.<sup>143</sup>

### Other Problems

Ascent to high altitude may exacerbate problems in patients with underlying medical conditions.<sup>91–93,144,145</sup> In general, any

disease that can be worsened by hypoxia can also be worsened by ascent to high altitude. Patients with respiratory illness such as asthma or COPD appear to be at increased risk of exacerbation of their disease and development of altitude-related medical illness. However, there are few studies that assess the specific risk for such patients who ascend to the types of moderate or high altitudes generally associated with tourist travel. Patients with any form of pulmonary hypertension are likely to be especially prone to the effects of altitude. It would therefore seem advisable to recommend avoidance of travel to high or very high altitude for patients with significant respiratory illnesses unless absolutely necessary. In addition, patients who elect to undertake treks or travel to high altitude should travel with a person who understands the symptoms and signs of, and therapeutic options for, altitude-associated illnesses. Furthermore, these patients should be especially careful to program gradual ascent into any trip that requires even a short stay at moderately high, or higher, altitudes.

Similarly, patients with significant cardiac disease (congestive heart failure, coronary artery disease, dysrhythmias, etc.) and patients with severe hypertension are also theoretically at risk of increased problems at high altitude. A few small studies and anecdotal reports indicate that patients with well-controlled angina or otherwise stable cardiovascular disease can ascend to moderately high altitude without adverse effects.<sup>87,88,91–93,100,102,145</sup> However, no controlled studies of travelers have been performed. Therefore, patients with significant but stable cardiovascular disease must be carefully counseled as to risks and potential therapeutic interventions when considering a trip involving exposure to moderate or high altitude.

### JET LAG

Most living organisms have evolved mechanisms enabling them to sense the day–night cycle.<sup>146–149</sup> Humans are no exception, and many of our physiologic values appear to have circadian patterns. The relationship between exogenous environmental clues and endogenous physiologic rhythms results in a carefully regulated cycle of most of these physiologic functions.<sup>146–149</sup> When there is a conflict between perceived external cues and ongoing internal rhythms, a variety of unpleasant symptoms are produced. A common form of conflict exists when a traveler crosses several time zones, resulting in a syndrome known as jet lag or “time zone fatigue.”<sup>146–151</sup> Body rhythms that are tightly regulated by environmental cues such as cycles of light and dark can adjust relatively rapidly after arrival in a new time zone. On the other hand, strong endogenous and light-insensitive internal rhythms may take much longer to readjust. It is known that the syndrome of jet lag is associated with actual change of time zone and not merely air travel because jet lag is only observable with east–west travel across time zones. Jet lag per se does not occur even with lengthy north–south travel.

The most common symptoms of jet lag include difficulty falling asleep, altered states of wakefulness, fatigue, lightheadedness, mild disorientation, anorexia, and mild to moderate forms of gastrointestinal upset.<sup>146–149</sup> In general, travel from west to east is associated with more severe symptoms than travel in the opposite direction. Acclimatization to the new time zone depends on the number of time zones crossed in travel. In general, a decrease

in symptoms and improvement of normal sleep–wake phases usually occur within 1 to 4 days. Time acclimatization can be accelerated by certain behavioral changes, such as outdoor activity in sunlight.

Evidence suggests that it may be possible to alleviate many of the symptoms of jet lag by resetting certain aspects of normal circadian rhythm pharmacologically.<sup>146,147,149,151</sup> The use of a short-acting and relatively nonsedating hypnotic agent (such as zolpidem 10 mg or temazepam 15 mg at bedtime) for a few days after arrival can be helpful in alleviating transient insomnia associated with jet lag.<sup>152,153</sup> Some researchers have suggested the use of the hormone melatonin in alleviating jet lag symptoms and rapidly enhancing time zone acclimatization. Melatonin is an important regulator of the sleep–wake cycle, and most studies have indicated that nightly administration of 3 to 5 mg of melatonin begun just before or on the day of arrival can significantly reduce the severity and duration of jet lag.<sup>153–158</sup> Nearly all of these studies were performed using pharmaceutical formulations of melatonin available in Europe. Melatonin is marketed in the United States only as a nutritional supplement. Therefore, although the use of melatonin at bedtime for 3 to 5 days beginning on the night of arrival has possible benefit for jet lag, the complete safety and efficacy of the formulations available in the United States have not been determined.

## NATURAL DISASTERS

Extreme variations in the climate can have sudden, severe, and long-lasting effects on the health of the resident and transient populations of the affected areas.<sup>159–164</sup> The most commonly recognized forms of natural disasters occur yearly in many diverse areas of the world (Box 134-2). Although the impact of such disasters occurs globally, the worst damage and loss of life are often greatest in the poorest and most underdeveloped countries. The public health impact of such events is usually far-reaching and ranges from disruption of infrastructure to outbreaks of communicable diseases.<sup>159–164</sup>

On December 26, 2004, a magnitude 9.0 earthquake occurred under the Indian Ocean near the Indonesian island of Simelulue. It was the largest magnitude earthquake recorded in the world since 1964.<sup>165</sup> The force generated from the earthquake spawned a series of tsunamis that devastated coastal areas and islands of many countries, including Indonesia, Thailand, India, and Sri Lanka. Damaging effects

of tsunami wave action were observed as far away as Kenya and South Africa. As of January 2005, more than 225,000 people were reported dead; millions of others were injured, became ill, or were displaced from their homes. This event is recognized as the deadliest tsunami in recorded history. Although the data are not yet available, it is very likely that more world travelers from industrialized countries will have died or become injured or ill from the results of this single event in 2005 than from all other forms of travel-related illnesses combined.

Health hazards due to tsunamis are numerous and known to occur in many other types of natural disasters as well.<sup>159–166</sup> The initial impact is due to loss of life from drowning, flooding, and destruction of homes, buildings, and vehicles. To compound matters, disruption of communication, transportation, and health-care delivery systems means that many injured or ill will die of otherwise treatable conditions. In the days following the event, damage to water and sanitation systems leads to the risk of waterborne diseases, such as viral gastroenteritis, cholera, dysentery, typhoid, and hepatitis A. In tropical and even temperate areas, flooding and disruption of water reservoirs can provide new breeding areas for insects, potentially promoting outbreaks of serious mosquito-borne diseases, such as malaria, yellow fever, and viral encephalitis. Although commonly labeled as high-risk sources of communicable disease outbreaks, the actual risk of disease associated with decomposing animal or human corpses appears to be minimal.<sup>167,168</sup> The sickest victims are often transported to cities outside the damage zone, increasing the risk of epidemic spread of certain forms of diseases. Because tsunamis, as well as most other types of natural disasters, can occur in otherwise low-risk and well-developed resort areas within tropical countries, all travelers need to be aware of the potentially lethal effects of natural disasters, even though the risk of occurrence is low.<sup>169</sup>

# Delusional Parasitosis

KATHRYN N. SUH  
JAY S. KEYSTONE

## INTRODUCTION

Delusional parasitosis (DP) is a rare disorder in which affected individuals have the mistaken but unshakable belief (delusion) that they are infected by “bugs”: parasites, worms, bacteria, mites, or other living organisms. As with all delusions, this belief is unfounded and irrational but cannot be corrected by reasoning, persuasion, or logical argument. The spectrum of symptoms leading to consideration of the diagnosis of DP can be broad and may encompass a range of symptoms and beliefs. Some individuals are quite functional and merely have the feeling that they are infested, others may experience the sensation of crawling or moving insects in their skin (formication), and yet others may have true delusions of parasitic infection that interfere with their usual activities to varying degrees.<sup>1</sup>

Delusional parasitosis is known by many names. Other English terms that have been used include Ekbohm syndrome (not to be confused with Wittmaack-Ekbohm syndrome, or restless legs), delusory parasitosis, psychogenic parasitosis, delusional infestation, delusional ectoparasitosis, formication, chronic tactile hallucinosis, dermatophobia, parasitophobia, and cocaine bugs.

## HISTORICAL PERSPECTIVE

The first reported case of what is now referred to as DP is credited to George Thibierge, who coined the term *acarophobia* in his 1894 description of patients who were convinced they were infected with mites.<sup>2</sup> In 1938, Karl Ekbohm described a similar clinical picture that he called “*praeseniler Dermatozoenwahn*” (presenile dermatozoic delusion),<sup>3</sup> subsequently referred to as Ekbohm syndrome. He postulated that abnormal sensations experienced by his and several other patients subsequently led to delusions that parasites were present. This theory was supported over 30 years later by Berrios, who also suggested that the initial sensation *as if* something is crawling on the patient’s skin leads to the conviction that something really is crawling on the skin.<sup>4</sup>

In 1946, Wilson and Miller described a total of 45 cases reported up to that time in addition to six cases of their own and introduced the term “delusional parasitosis.”<sup>5</sup> Bers and Conrad proposed the term “chronic tactile hallucinosis” in 1954, because the similarities they observed with alcohol

included hallucinosis.<sup>6</sup> Munro suggested that DP was in fact a form of monosymptomatic hypochondriasis or monosymptomatic hypochondriacal psychosis (MHP), a fixed, single hypochondriacal belief that exists when no other disorder of thought is present.<sup>7</sup> By 1995, in an extensive review of the topic, Trabert<sup>8</sup> had identified 1223 cases in the literature. Many additional case reports and case series have since been reported.

## PSYCHIATRIC PERSPECTIVE

The interaction between psychiatric symptoms and dermatologic conditions has been well described.<sup>9–11</sup> It is estimated that 30% to 40% of patients seen in dermatology clinics have some psychiatric symptoms.<sup>12</sup> This is not to suggest, however, that psychiatric illness is the *cause* of dermatologic symptoms in all such patients. Koo has described three forms of psychodermatologic conditions in which disorders of skin and mind may be intermingled<sup>9</sup>: psychophysiologic disorders, in which the patient’s mental state can directly affect the condition of an underlying skin disease (e.g., eczema worsened by stress); primary psychiatric disorders such as DP, in which cutaneous symptoms or findings can be directly attributed to an underlying psychiatric disease; and secondary psychiatric disorders, such as anxiety or depression, that may result from an intractable disfiguring skin condition (e.g., alopecia, ichthyosis).

In its truest form, DP is a delusional disorder of the somatic type: “delusions that the person has some physical defect of general medical condition.”<sup>13</sup> Nonexistent disease or alteration of the body forms the basis of a somatic (or somatoform) delusional disorder. Delusions of parasitosis are classified as an MHP and are the most common form of this disorder; others include delusions of dysmorphism and delusions of body odor or halitosis.

The etiology of somatic disorders such as DP and the mechanisms of its persistence in affected individuals are unknown. One hypothesis is that for some individuals, distressing symptoms become amplified and are then perpetuated following the result of newly acquired knowledge or awareness of a disease, new or renewed public health interest, or intense media coverage, for example.<sup>14</sup> Fleeting pruritus following an encounter with an individual with scabies may not be uncommon, but for some the pruritus might worsen as they learn more about scabies. The reasons for this degree of symptom amplification are unclear. Some individuals may truly believe that they are sick, others may behave this way because they think that is how they are expected to behave, and others may be seeking secondary gains.<sup>14,15</sup> Regardless, symptoms are continuously intensified with the resulting perception that the individual is now suffering from a serious disease. Patients may also develop a heightened awareness of and misinterpret new sensations or symptoms that they were previously oblivious to, reaffirming their beliefs that they must be sick, and perpetuating the cycle. As with dermatologic disease, stress can also exacerbate other somatic complaints, and the stress induced by the severity of the perceived illness may also act to augment it further.

## CLASSIFICATION OF DELUSIONAL PARASITOSIS

No definitive classification of DP exists.<sup>16</sup> However, in broad terms, three different forms can be described based on

published accounts.<sup>17</sup> Primary psychotic DP exists when the delusion of parasitic infection is the only manifestation of disease; that is, no other psychiatric or psychological disorder is present. Secondary DP may occur in the presence of underlying psychiatric disease, such as schizophrenia or depression. Delusions of parasitosis may also be features of underlying medical illnesses and intoxication or substance abuse (e.g., cocaine), and rarely have been described as adverse effects of some prescription medications.

### Primary Delusional Parasitosis

As noted previously, primary DP refers to a somatic delusional disorder. By definition, patients with delusional disorders do not meet all criteria required for the diagnosis of schizophrenia.<sup>13</sup> Specifically, hallucinations, disorganized speech, schizophrenic behavior, and other “negative” symptoms should be absent, although hallucinations that are clearly related to the delusional theme (i.e., tactile hallucinations) may be present. Sufferers of DP and other forms of MHP generally have intact mental function, lack other manifestations of psychiatric disease, and have otherwise normal behavior. Their delusions are limited in scope and generally do not encroach on personal and professional aspects of their lives. Criteria for the diagnosis of delusional disorders are shown in Table 135-1.

Strictly speaking, DP differs from hypochondriasis in that individuals with the latter condition recognize that fear of illness or disease is unfounded, and it differs from phobias in that patients with DP do not have a fear of becoming ill—they believe they *are* ill. Underlying psychiatric disorders, including schizophrenia and mood disorders, and pre-existing medical conditions (including true parasitic infections!), substance abuse, and drug side effects must be ruled out prior to establishing a diagnosis of primary DP. Other mood disorders (e.g., anxiety, depression) may be present with primary delusions of parasitosis, but they must clearly be secondary to the delusional disorder in order to classify the delusional disorder as primary DP.

**Table 135-1** Diagnostic Criteria for Delusional Disorder

- Patient has nonbizarre delusions involving situations that occur in real life, lasting longer than 1 month
- Patient does not meet all criteria for diagnosis of schizophrenia
- Patient's function is otherwise not markedly impaired
- Patient's mood episodes, if concurrent, are brief compared with duration of delusions
- Substance abuse, medication side effects, and medication use in general must be ruled out

Adapted from American Psychiatric Association: DSM-IV-TR: Diagnostic and Statistical Manual of Mental Disorders, 4th ed., Text Revision. Washington, D.C., American Psychiatric Association, 2000, pp 323–329.

### Secondary Delusional Parasitosis

Delusions of parasitosis may occur in conjunction with other psychiatric symptoms. Some patients with DP are clearly schizophrenic. Others have varying degrees of psychiatric illness including anxiety, depression, obsessive-compulsive disorder, schizophreniform disorder, bipolar disorder, or a family history of psychiatric illness.<sup>15,18,19</sup> One case has been described in the setting of post-traumatic stress disorder.<sup>20</sup> Delusions of parasitosis in the setting of underlying psychiatric disease must be distinguished from primary DP because the management differs; however, differentiating these conditions may be challenging, particularly for the family physician or dermatologist, who is most likely to encounter such patients. Phobias and hypochondriasis may present with apparent delusions of parasitosis and may be considered secondary delusional parasitosis by some.<sup>18</sup>

### Delusions of Parasitosis Associated with Underlying Medical Conditions

Up to 25% of cases of DP have been attributed to underlying medical diseases.<sup>8,21</sup> Establishing whether delusions are related to an associated medical disorder, drug, or toxin may be critical, since treatment of the condition (or withdrawal of the offending agent) may lead to resolution of delusional symptoms.

Central nervous system (CNS) disorders appear to be the most common underlying medical conditions associated with DP. Delusions have been described in the setting of dementia of various etiologies,<sup>21,22</sup> head injury,<sup>23</sup> cerebrovascular accidents,<sup>23,24</sup> multiple sclerosis,<sup>23</sup> multiple system atrophy,<sup>25</sup> and CNS infections including encephalitis, meningitis, and neurosyphilis.<sup>21</sup>

In addition, DP has been associated with diseases of most other organ systems including the hematopoietic,<sup>23</sup> pulmonary,<sup>23</sup> cardiac,<sup>5,26</sup> renal,<sup>23</sup> gastrointestinal,<sup>23</sup> and endocrine.<sup>22,23,27</sup> Nutritional deficiencies including vitamin B<sub>12</sub>,<sup>23,28</sup> folate,<sup>21,23</sup> and pellagra<sup>23,29</sup> have also been reported as causes of DP. Delusions of parasitosis may also be a manifestation of a variety of malignancies<sup>21,27,30</sup> or systemic infections such as human immunodeficiency virus infection,<sup>31</sup> tuberculosis,<sup>5</sup> and leprosy.<sup>22</sup>

Substance abuse is another precipitant of parasitic delusions and should be considered, particularly when DP presents in younger age groups.<sup>19,23</sup> In such instances, the delusions are usually transient and of inadequate duration to meet the criteria for delusional disorder. Cocaine, alcohol, and amphetamines (e.g., Ritalin) are common precipitants.<sup>32</sup> Rarely, prescription drugs may induce delusions of parasitosis; DP has been reported with the use of phenelzine,<sup>33,34</sup> pargyline,<sup>34</sup> ketoconazole,<sup>35</sup> and corticosteroids.<sup>21</sup> Drug-induced DP generally resolves once the offending drug is discontinued. A more thorough list of medical conditions and drugs/toxins associated with DP is shown in Table 135-2.

### EPIDEMIOLOGY

Delusional disorders in general are rare.<sup>36</sup> The incidence and prevalence of delusional disorders have been estimated to be 0.7 to 3.0 and 24 to 30 cases per 100,000 population (upper limits of 0.003% and 0.03%), respectively,<sup>37</sup> although

**Table 135-2 Medical Conditions Associated with Delusional Parasitosis**

Adapted from Slaughter JR, Zanol K, Rezvani H, et al: Psychogenic parasitosis: A case series and literature review. *Psychosomatics* 1998; 39:491–500; and Johnson GC, Anton RF: Delusions of parasitosis: Differential diagnosis and treatment. *South Med J* 1985;78:914–918.

the rates in this study were not determined using currently accepted diagnostic criteria. Males and females are almost equally affected, with delusional disorders being slightly more common in women.

The exact rates of DP are even more difficult to determine. A retrospective study of almost 10,500 psychiatric outpatients in China identified 86 (0.83%) with delusional disorders, two of whom had unspecified somatic delusions.<sup>38</sup> In a Norwegian study of over 3000 psychiatric admissions to hospital, 0.4% of patients with paranoid psychoses had hypochondriacal delusions.<sup>39</sup> However, because patients with DP insist that their symptoms do not have a psychiatric basis and hence

refuse to seek psychiatric help, the true incidence and prevalence of this disorder may be greatly underestimated in the psychiatric literature. Trabert estimated the incidence and prevalence of DP to be 16.6 and 83.2 cases per million population per year, respectively, in southwest Germany.<sup>40</sup> Although the number of reported cases of DP in the literature continues to increase, it remains extremely uncommon. Based on Lyell's retrospective survey,<sup>23</sup> Lynch estimated that a practicing dermatologist could expect to see one patient with DP for every 7 years in practice.<sup>1</sup> Most cases have been reported from centers in North America and Europe and more recently from Asia.

## CLINICAL FEATURES AND PRESENTATION

General characteristics of patients with DP are fairly consistent based on data reported in two physician surveys<sup>23,26</sup> and several case series.<sup>8,19,21,22</sup> Delusional parasitosis can affect patients of all ages but is more common in older age groups (>50 years).<sup>8,26</sup> The mean age of onset in 802 patients for whom this was recorded in Trabert's review of 1228 cases was 57 years<sup>8</sup>; 84% of patients were over age 50. The age of onset does not differ significantly between men and women, although men tend to be slightly younger.<sup>8</sup> In all age groups, the disorder appears to be more common in women; overall, women outnumber men by roughly a 2–3:1 ratio.<sup>8,22,23</sup> Although the sex distribution is almost equal in early adulthood, the preponderance of women in older age groups is striking, with the female-to-male ratio exceeding 3:1 in individuals over 50 years of age.<sup>8,23</sup> Patients in younger age groups are more likely to have an underlying cause for their delusions, notably, head injuries, substance abuse, and schizophrenia, and are more likely to be involved in shared delusions.<sup>19,23</sup>

Patients with primary DP are usually otherwise functional individuals who do not have an antecedent history of psychiatric illness. For some patients, the delusions may be triggered by an event in which possible exposure to parasites may have occurred, (e.g., sleeping in unclean bedsheets or borrowing someone else's clothes).<sup>1</sup> Travel to and receipt of gifts from exotic destinations have precipitated DP.<sup>41,42</sup> Documented parasitic infections predate the development of DP in only 2% of cases.<sup>23</sup> Patients may be from any socioeconomic background. Many affected individuals are highly functional and highly educated; in Lyell's survey,<sup>23</sup> several of the 282 patients described were professionals, including physicians and psychologists. Despite this, they are, by definition, unable to appreciate their delusional state, although in some cases of primary DP, the unfounded basis of the patient's delusions has become apparent to the individual during the course of pharmacologic treatment.<sup>32</sup>

Many patients are single and have been categorized as "loners."<sup>7,43</sup> In Trabert's series, only 21% of the 67 patients for whom social interactions were described were considered to have "good and stable social contacts"; 54% were considered "socially isolated."<sup>8</sup> Social isolation appears to be a premorbid state rather than a consequence of illness.<sup>8</sup> A higher-than-expected prevalence of personality disorders has also been observed in some case series.<sup>21,23</sup>

Patients with DP often have a long history of dermatologic complaints including rashes, pruritus, and sensations of stinging, biting, and formication. The onset is usually insidious, and

most patients have symptoms for at least 6 months and often many years before the diagnosis is made.<sup>8,22</sup> In Trabert's review, the average duration of symptoms was 3 years and the median duration 1 year.<sup>8</sup> Typically, patients have sought the help of multiple physicians (most commonly primary care physicians and dermatologists, sometimes infectious diseases physicians, rarely psychiatrists) or entomologists, usually with little satisfaction. Those who attribute their illness to household pets may have visited veterinarians repeatedly, seeking treatment for their pets. Many patients have received repeated courses of dermatologic and antiparasitic therapies, despite the lack of an objective diagnosis. They often bring in specimens for examination that they have picked from their skin—the “matchbox sign,”<sup>44</sup> which more recently has been aptly referred to as the “Ziploc bag sign.”<sup>18</sup> Occasionally, these containers will contain parts of nonpathogenic insects, but most often they will harbor normal skin flakes or dust, hair, or other “flotsam of normal life.”<sup>15</sup>

Patients may provide bizarre and unlikely stories concerning their infestation, including exhaustive descriptions and diagrams of the parasites' appearance, habitat, entry and egress to and from various body cavities, and reproductive cycles. Patients can often enumerate the parasites and provide details of their activities. Many have repeatedly called exterminators into their homes, consulted pest-control services, and sprayed themselves and their homes with potentially toxic pesticides and other chemicals to eradicate the bugs. Those driven to extremes may move or rid themselves of some or all of their belongings in the hopes of ending the problem. The fear of contagion and transmission of disease to others may or may not be present.

Other persons occasionally are drawn into the patient's delusional system; 8% to 25% of delusions of parasitosis may be shared.<sup>21,23,45,46</sup> Delusions are most often shared with one other person (*folie à deux*), usually a partner or spouse, or less commonly with offspring,<sup>23</sup> and usually are induced by a woman.<sup>46</sup> On occasion, trios (*folie à trois*) or even larger groups, such as entire families or groups of occupational colleagues, have developed shared delusions.

Apart from the firm belief that they suffer from a parasitic infection, the behavior of affected patients is usually unremarkable. Physical examination is often unrevealing apart from ulcers, excoriations, and scars that result from attempts to remove the organisms from the skin by using fingernails, knives, pins, or other objects. On exposed skin, lesions may be asymmetric, reflecting the increased range of the patient's dominant hand; this may be particularly evident over the shoulders and scapulae.<sup>23</sup> Contact or irritant dermatitis resulting from excessive cleaning or the use of abrasive soaps or chemicals may be present.

## MANAGEMENT

### Approach to the Patient with Delusional Parasitosis

The diagnosis of DP should be suspected when an individual has an irrational, fixed belief that he or she is infected with internal or external parasites despite reassurance and ample evidence to the contrary. Clearly, it is important to determine the following: (1) is the belief founded in reality? (i.e., is the patient really infected?); (2) if infection can be reliably excluded, is the patient truly delusional, or is the belief “shakable”? (is the patient merely hypochondriacal and can the patient possibly

be convinced that he or she may not be infected?); and (3) if the patient is delusional, which form of DP is present? (i.e., primary DP, secondary DP, or DP associated with underlying medical illness or medications/toxins). Therapy differs markedly depending on the answers to these three questions. Clearly, treatment of a previously undiagnosed parasitic infection or of an underlying medical condition (if possible) is indicated if either is present. If the patient is truly delusional and an organic cause can be ruled out, the major challenge is to determine whether the patient has a primary delusional disorder (i.e., MHP) or an underlying psychiatric illness (i.e., secondary delusions of parasitosis). A psychiatric opinion is invaluable in such instances, but it is often never obtained, since patients with DP usually refuse a psychiatric assessment.

One key to the management of patients with DP is the development of a strong, therapeutic relationship. A significant proportion of these patients, if not the majority, express dissatisfaction with previous physicians, whom they believe are incompetent and uncaring. As a result, patients often fail to attend follow-up appointments and receive inadequate or no therapy, whereas many could benefit from readily available and effective therapy if only they would take it. A sympathetic ear, a nonjudgmental approach, acknowledgment that the patient's symptoms are real, and empathetic exploration into the effects of their symptoms on their daily lives can instill a sense of trust into the relationship.<sup>47</sup> It has been debated whether the physician should overtly agree or disagree with the patient's beliefs,<sup>15</sup> but many authors suggest a conservative and nonconfrontational approach.<sup>1,15,48,49</sup> Use of phrases such as, “I cannot see any parasites today” rather than “there are no parasites,”<sup>23</sup> and acknowledgment that the problem *may* have resulted from a previous infection<sup>18</sup> (perhaps even stating that the persistent symptoms are due to a “chemical imbalance”) may accomplish this while at the same time gaining the patient's trust. It is important not to dismiss patients' complaints as trivial, even when it is obvious that they are delusional, but probably equally important not to overtly support their beliefs and feed into their delusional system. Reassurance that they can be helped also is valuable.

Initial assessments should focus on the patient's primary complaints, attempting to rule out true infection and organic causes of symptoms. A thorough history, including use of prescription and illicit drugs, and review of systems should be obtained. Listening carefully to the patient's answers sometimes provides clues to underlying psychiatric or medical illness. A complete physical examination is warranted, with particular attention paid to the skin, since most patients have cutaneous symptoms. Careful assessment of any skin lesions is essential; in a small number of cases, patients believed to have DP in fact have a true parasitic infection. Evaluation by a dermatologist, if not already performed, can be beneficial to the primary care physician and may also provide reassurance to patients that their symptoms are being taken seriously. If the patient has brought in specimens, reassure the patient that they will be sent to a proper laboratory or entomologist for examination. To avoid the argument that the “parasites” have been or will be missed because of improper preservation, provide the patient with specimen bottles containing preservative for subsequent samples. Skin biopsies may rarely be indicated in some instances; skin scrapings or other cutaneous specimens may be more appropriate and can be readily obtained during an

office visit. Negative results, especially from repeated examinations of submitted specimens, can eliminate the possibility of a real parasitic infection.

Possible organic causes of DP may be evident from the history or physical examination (e.g., hyperthyroidism, neurologic disease). Blood work should be obtained to complete the assessment. Appropriate initial investigations include a complete blood count and differential, electrolytes, urea, creatinine, liver function tests, fasting blood sugar, thyroid-stimulating hormone level, and B<sub>12</sub> and folate levels, as well as a chest radiograph. Based on the individual's risk factors, additional tests such as serology for human immunodeficiency virus infection, tuberculosis skin testing, VDRL or rapid plasma reagin test, or other radiologic imaging (e.g., computed tomography or magnetic resonance imaging of the brain), may be indicated. Those with organic diseases may be better managed by referral to an appropriate specialist (e.g., internist, neurologist). By means of a thorough history and physical examination and some basic investigations, true infestation and the more commonly reported medical conditions associated with DP can be eliminated.

Over the course of several visits, serial examination of skin lesions can be performed and additional specimens (or other investigations) obtained as required. In addition, follow-up visits provide the opportunity for the patient to develop more trust in the physician. Trust in the physician is crucial if a psychiatric referral is likely to be required. Repeated assessments of the patient are helpful in determining whether the patient has a shakable belief (hypochondriasis) rather than true delusions; he or she may eventually question whether the problem might be imaginary or "in his or her head," or ask the physician's opinion of the problem.<sup>18</sup> Such shakable beliefs are often associated with anxiety or depression;<sup>18</sup> supportive therapy and anxiolytic or antidepressant therapy are required for these patients. In contrast, antipsychotic therapy is usually indicated for patients with primary delusional parasitosis.

### Treatment of Organic Causes of DP

Any real infestation should be treated appropriately. If an underlying organic cause is diagnosed, treatment may lead to resolution of the delusions<sup>29</sup>; input from other specialists may be indicated. Any medications or toxins that may be implicated should be discontinued as soon as possible if this is feasible.

### Psychiatric Assessment

Once true infestation has been excluded, a psychiatric referral is warranted. Effective therapies are available for both primary and secondary DP, but they differ. Delusions of parasitosis associated with underlying psychiatric disorders such as schizophrenia or depression require treatment of the underlying disorder; this is probably best managed by a psychiatrist and is not discussed further. Although delusions in some patients who have organic causes of DP may improve or resolve with treatment of the underlying condition, these individuals may also benefit from psychiatric care. Gould and Gragg<sup>50</sup> suggest that psychiatric evaluation is appropriate only for selected patients with DP (such as those with schizophrenia) and that many others can be adequately managed by primary care physicians or dermatologists lest they be lost to medical care altogether by the suggestion that they see a psychiatrist. However, many

authors suggest that a psychiatrist at least be consulted at some point in the patient's care.<sup>18,19,32</sup> Regardless of the approach, the treating physician's credibility often dissipates at the mention of the need for psychiatric consultation or therapy.

A thorough psychiatric assessment can provide confirmation of (or establish) the diagnosis; this is perhaps the most important reason for referral, and it allows determination of the most appropriate form of therapy. Another reason for psychiatric referral is that family physicians and dermatologists generally are neither trained nor prepared to provide the psychotherapy and pharmacotherapy that can benefit both the hypochondriacal patient (without true delusions) and the patient with primary or secondary DP. Many hypochondriacal patients will agree to a psychiatric assessment, but most patients with DP will not; therefore, tact and careful strategy are required.

Convincing patients with DP of the need for and importance of a psychiatric referral is extremely difficult. Gradual introduction of the topic over the course of several office visits, with emphasis on the need for expert guidance to manage the effects that DP has had on the patient's life, may result in greater success. Acceptance of psychiatric referral is likely to be higher if an on-site psychiatrist is present to perform an immediate assessment, such as in a dermatology-psychiatry liaison clinic, rather than asking the patient to attend a separate appointment in a different place.<sup>18,32,50</sup> but a significant proportion of patients will refuse even in this setting.<sup>32</sup> Furthermore, this arrangement often is not practical for physicians practicing outside of academic centers. At a minimum, if a psychiatric evaluation cannot be obtained for any reason, the case should be discussed with a psychiatrist prior to commencement of any therapy.

### Treatment of Primary Delusional Parasitosis

Psychotherapy, psychosurgery, and electroconvulsive therapy have had relatively little success in the treatment of DP.<sup>30</sup> Psychotherapy has been successful in only 10% of cases, similar to the rate of resolution in untreated patients.<sup>15</sup> Antidepressant and anxiolytic medications may be beneficial if delusions are attributable to a pre-existing depressed or anxious state but have little or no role in the treatment of primary DP. Secondary mood disorders (i.e., those that are a consequence of the delusional state) may be improved, but delusions will persist. Prior to the introduction of effective neuroleptic therapy, DP was considered to be a progressive disorder with a low rate of spontaneous remission.

Treatment of primary DP was revolutionized by the advent of atypical antipsychotic medications. However, no clinical trials have examined the efficacy of neuroleptic medications for the treatment of DP. Nonetheless, if the diagnosis has been established with certainty, antipsychotics are now the mainstay of therapy. Convincing patients to take these medications provides yet another obstacle in the management of this disorder. Even if patients agree to start medication, adherence may be a problem. Occasionally, bargaining with a patient might work, whereby the physician agrees to a patient's request (e.g., treatment with an antiparasitic agent) on condition that the patient also takes antipsychotic medication.<sup>18</sup> Patients often refuse to try such drugs as risperidone or pimozide if they discover that they are antipsychotic agents. The physician can warn the patient that the agent is commonly used for schizophrenia and indicate that "of course, you are not schizophrenic!"

Patients are more likely to agree to take medication for treatment of a “chemical imbalance” than for a psychiatric problem. The physician can provide examples of other medications that have multiple indications for their use, such as aspirin for pyrexia and coronary artery disease, or amitriptyline for depression and neuritis. Some, particularly those insistent on knowing whether medication will cure their problem, may be persuaded to try medication if they are told that other patients with similar conditions have experienced great relief from symptoms and improvement in their well-being.

Before the introduction of atypical antipsychotics (such as ziprasidone, clozapine, risperidone, olanzapine, and quetiapine), pimozide was frequently used as first-line therapy for DP. However, today, many psychiatrists would choose the newer antipsychotics over pimozide because of their better safety profile and more specific actions.

### Pimozide

Pimozide has been the most extensively used antipsychotic agent and has had the greatest reported success rate for treatment of DP. The first reports of successful treatment of MHP were published in 1975.<sup>51,52</sup> Shortly thereafter, small case series of patients with DP who were successfully treated with pimozide were published.<sup>7,53</sup> Subsequent case series have documented the effectiveness of pimozide, with up to 87% of patients demonstrating some response (33% to 52% complete, 28% to 35% partial), although such data should be interpreted with caution as they are observational only.<sup>21,54</sup> In the two retrospective physician surveys, pimozide was reported to induce a clinical response in 73% and 81% of treated patients,<sup>8,23,26</sup> with a full remission in 50%.<sup>8,23</sup> Although, like other retrospective studies, these results are prone to inherent bias. One placebo-controlled, double-blind trial with 10 patients<sup>55</sup> and another double-blind, crossover trial with 11 patients<sup>56</sup> both demonstrated efficacy of greater than 90%.

Pimozide is an oral diphenylbutylpiperidine antipsychotic agent. It is related in structure to butyrophenones, of which haloperidol is the most well known. The mechanism of action is selective blockade of dopamine type 2 receptors; it has minimal effect on other CNS neurotransmitters, although its antagonistic effects on opiate receptors may contribute to reducing the sensations of pruritus and formication.<sup>55</sup> Other pharmacologic effects of pimozide include a mild anticholinergic effect, blockage of calcium channels and of some adrenergic receptors, and induction of prolactin secretion. The most common adverse effects of pimozide when used at therapeutic doses are extrapyramidal reactions (tremor, bradykinesia, shuffling gait), which occur in up to 15% of patients.<sup>19</sup> Prolongation of the QT interval with the possibility of fatal arrhythmias may occur, particularly with higher doses of the drug; therefore, a baseline electrocardiogram is recommended prior to starting pimozide and periodically during therapy to monitor the QT interval duration. Increase of the QT interval by 25% or more from baseline, or a QT interval of greater than 520 msec, warrants temporary cessation of the drug and a subsequent dose reduction. Acute dystonic reactions, akathisia, anticholinergic effects, orthostatic hypotension, and galactorrhea are other side effects of pimozide.

Doses between 1 and 12 mg daily are usually effective for treatment of DP. Pimozide should be instituted at a low dose

(0.5 to 1 mg daily) and increased gradually (e.g., by 1 mg weekly) either until the desired clinical effect is achieved<sup>19</sup> or to the maximum recommended dose of 20 mg/day. The lowest effective dose of pimozide should be used to minimize the risk of adverse events, ideally no more than 10 mg/day. Once a satisfactory response has been obtained, which may require several weeks of therapy, the patient should be maintained on the same dose for at least one and preferably several months.<sup>19,57</sup> The dose should then be tapered gradually (by 1 mg every 1 to 2 weeks) until it is discontinued, with careful observation for relapse.<sup>19,57</sup> If relapse occurs, it often responds to reinstitution of the drug; some patients will require prolonged therapy in order to control symptoms.

### Other Antipsychotic Agents

Neuroleptic agents other than pimozide have been used with success in the treatment of DP but have not been reported to the same extent. In view of the cardiotoxic effects of pimozide, however, other agents may be preferable, particularly in the elderly and those with known cardiac disease. Furthermore, a more recent small case series has questioned the effectiveness of pimozide for treatment of delusional disorders such as DP.<sup>58</sup>

Haloperidol, similar in structure to pimozide, has been used successfully.<sup>18,32,59</sup> Risperidone has been effective in small numbers of patients, including some for whom haloperidol and pimozide have not been effective.<sup>60–63</sup> Serotonin is believed to play a significant role in psychosis<sup>64</sup>; risperidone is one of several atypical antipsychotic agents that preferentially blocks serotonin receptors while still maintaining some activity against dopamine receptors. Because of its lower toxicity compared with pimozide, some authors consider risperidone to be the first-line therapy for treatment of DP.<sup>65</sup> Between 0.25 and 5 mg daily, administered in one or two doses, have been required for clinical response.<sup>60,61,63</sup> Adverse effects including extrapyramidal reactions can occur, but overall risperidone appears to be safer and better tolerated than pimozide.<sup>65</sup>

Other antipsychotic agents that have been used with success include chlorpromazine,<sup>66</sup> olanzapine,<sup>67,68</sup> perphenazine,<sup>27</sup> quetiapine,<sup>63</sup> sertindole,<sup>69</sup> sulpiride,<sup>70</sup> thioridazine,<sup>71</sup> and trifluoperazine.<sup>66</sup>

### OUTCOME AND PROGNOSIS

Delusional parasitosis was previously considered a progressive disorder with little chance of spontaneous improvement; only 10% to 30% of cases would remit spontaneously prior to the use of neuroleptics.<sup>8,15</sup>

The duration of symptoms is directly associated with the outcome of therapy; the longer the duration of symptoms, the less likely the patient will achieve a full remission.<sup>8</sup> Regardless, the use of effective pharmacotherapy has improved the prognosis for patients with DP. In Trabert's retrospective case series, 52% of patients who were followed after 1960 (i.e., after the introduction of neuroleptics for treatment) had a sustained remission during follow-up, compared with 33% who were diagnosed before 1960.<sup>8</sup> Outcomes related specifically to neuroleptic use were not addressed in this study, however. Other case series have demonstrated high

rates of full recovery using pimozide, with 50% to 90% of patients achieving a sustained remission.<sup>54,72</sup> An additional one-third of patients may respond well but without achieving full remission.<sup>23,54</sup> The relapse rate is difficult to determine, but relapses appear to be common<sup>23</sup>; however, they do tend to respond well to reinstitution of therapy, regardless of the neuroleptic agent used.<sup>18,23,27</sup>

# Tropical Infectious Disease Concerns in Pregnancy

RAUL E. ISTURIZ  
EDUARDO GOTUZZO

Tropical infectious diseases that occur during pregnancy, an otherwise healthy, life-affirming state, pose special risks to the mother and fetus. Furthermore, many diagnostic, therapeutic, and preventive measures often must be modified during pregnancy because of their potential for serious side effects. This chapter discusses tropical infectious diseases that, during pregnancy, are especially important to mother or fetus, or that are more common or severe when associated with gestation. The reader must bear in mind that every diagnostic, therapeutic, or preventive strategy applied to a pregnant woman must be individually weighted against the possible side effects both to her and to her developing infant once instituted.

Worldwide, approximately eight million women suffer complications related to their pregnancies every year, and over half a million maternal deaths result. Maternal and neonatal morbidity and mortality show a stark divide between developing and developed countries. In some tropical areas, such as sub-Saharan Africa and central South Asia, one woman in 16 may die of pregnancy-related complications. This compares unfavorably with an average of one in 2800 in developed countries. These figures may be an underestimation since the World Health Organization (WHO) estimates that maternal deaths are under-reported by as much as 50%. Tragically, motherless children are 10 times more likely to die in childhood than children whose mothers survive. Although maternal infectious diseases in the tropics have an important contributing effect on maternal and childhood morbidity and mortality, their actual impact is unknown.

Based on anecdotal clinical observations and perhaps rooted in a need to explain maternal tolerance of intrauterine fetal tissues, physicians have perceived that the maternal immune response must to some extent be suppressed during gestation. Other than diminished T- and NK-cell function, no measurable suppression has been found in maternal immunity. Neutrophil numbers and function, B-cell counts and subsets, immunoglobulin G (IgG), IgM, and IgA concentrations, antibody-dependent cellular cytotoxicity (ADCC), and complement have been found within the normal limits. Nevertheless, the mild immunosuppression that may accompany pregnancy but that does not last postpartum may play an as yet undefined

**Table 136-1** Risk Categories of Selected Antimicrobial Agents in Pregnant Women

Agent	Pregnancy Category*
Atovaquone-proguanil	C
Artemisinin	N/A
Azithromycin	B
Aztreonam	B
Chloroquine	N/A (C?)
Chloramphenicol	N/A (C?)
Clarithromycin	C
Cefoperazone	B
Cefotaxime	B
Ceftriaxone	B
Cycloserine	N/A (C)
Clindamycin	B
Dapsone	C

\*See Table 136-2.

role in maternal infectious morbidity and mortality by the diseases described in this chapter. The importance of direct or indirect exposure of pregnant women to microorganisms derived from poor tropical areas cannot be overemphasized.

Furthermore, the potential risks of anti-infective drugs in pregnancy also complicate the management of important tropical infectious diseases in pregnant and newborn individuals. The U.S. Food and Drug Administration (FDA) risk category definitions and assignments for selected antimicrobial agents are shown in Tables 136-1 and 136-2. As considered below, for malaria infections that are life-threatening to mother and fetus, the benefits of antimalarial agents and the lack of significant documented human toxicities for chloroquine, mefloquine, atovaquone-proguanil, and quinine, mandate their use.

## BRUCELLOSIS

Although teratogenicity has not been described, *Brucella* has been isolated from placental, fetal, and newborn tissues, demonstrating vertical transmission.<sup>1-3</sup> Epidemiologic evidence suggests that *Brucella* species, and *B. melitensis* in particular, can produce preterm and intrauterine fetal death followed by spontaneous abortions in humans, probably more frequently than do other bacterial infections.<sup>4</sup> An increased incidence of fetal loss among infected pregnant women with brucellosis has been repeatedly described.<sup>4-6</sup> In their review of 92 pregnant women with brucellosis in endemic Saudi Arabia, Khan and colleagues note that "although comparative

**Table 136-2** U.S. FDA Use-in-Pregnancy Ratings

Category	Interpretation	Comments
A	Controlled studies show no risk	No demonstration of risk to the fetus in any trimester
B	No evidence of risk in humans	The chance of fetal harm is remote, but remains a possibility
C	Risk cannot be ruled out	There is a chance of fetal harm, but the potential benefits may outweigh the potential risk
D	Positive evidence of risk	Fetal risk demonstrated, potential benefits may outweigh the risk
X	Contraindicated in pregnancy	Positive evidence of fetal abnormalities or risk that clearly outweighs any possible benefit

data are limited, the incidence of abortion from 10% to 42% in patients with active brucellosis exceeds that observed in patients infected with other organisms, such as *Campylobacter* species and *Salmonella* species, and suggests that *Brucella* species may indeed produce human abortions more frequently than do other bacterial pathogens.” They also recommend prompt antimicrobial therapy in pregnant women with brucellosis.<sup>4</sup>

The absence of erythritol in the human placenta, and anti-*Brucella* activity in human amniotic fluid, may explain why brucellosis causes fewer spontaneous abortions in humans than in farm animals, especially bovine species.<sup>7</sup> *Brucella* has also been isolated from human breast milk and from vaginal swabs from nonpregnant females, but the relevance of these findings remains uncertain.<sup>8–12</sup>

The clinical presentation of brucellosis during pregnancy has prognostic implications for fetal survival. In the Saudi study, during the first and second trimesters, vaginal bleeding with or without febrile illness was associated with spontaneous abortion in all cases of brucellosis, but patients who were treated because they presented with a predominantly febrile illness had no spontaneous abortions.<sup>4</sup> Of 11 patients who were treated because of febrile brucellosis presenting preterm during the third trimester, one spontaneous abortion was observed. Also one spontaneous abortion was documented out of 14 patients that presented with febrile brucellosis at term. The presence of bacteremia or high brucella agglutinin antibody titers did not correlate with the incidence of abortion. In this series, antibiotics used for treatment were trimethoprim-sulfamethoxazole (TMP-SMX) and rifampin.

In a series of studies in Peru, 97 pregnant women with brucellosis have been treated in Lima over a 25-year period.<sup>13,14</sup> Several presented with jaundice, one patient died of hepatic failure in her third trimester, and 7 had spontaneous abortions. Of 22 patients that were admitted to the hospital with threatened abortion, 6 had premature deliveries and 16 eventually delivered a term infant. In this series, rifampin was given for 6 weeks plus an aminoglycoside for the first 2 weeks. Treated patients had no abortions.

Combination treatment of brucellosis is effective,<sup>15–17</sup> but tetracycline is contraindicated in pregnancy. Antepartum treatment with active antibiotics prevents spontaneous abortion and current information seems enough to recommend treatment of all cases. During pregnancy, combination therapy with rifampin plus TMP-SMX provides the best therapeutic balance to cure the disease, prevent relapses, and protect the developing infant.

## CHOLERA

In endemic areas, but especially during epidemics and pandemics, adult individuals including pregnant women can and do acquire cholera.<sup>18–20</sup>

Among pregnant women, cholera is associated with diarrhea and dehydration of such severity that intrauterine suffering and death may occur. In 1892, 57% of pregnant women with cholera died and the abortion rate was estimated around 54%. Conversely, during a 1979–1980 cholera outbreak in Ile-Ife (Nigeria), where 61 pregnant patients were identified, cholera appeared to be less severe and to have a lower mortality in pregnant than in nonpregnant women.<sup>19</sup>

Cholera, a toxin-mediated disease without hematogenous spread or placental invasion, is not transmitted vertically, but intrafamilial transmission from adults with diarrhea is possible in the neonatal period. In Peru, among 626 children with cholera, isolation of *Vibrio cholerae* O1 was possible in 310 (49%), more commonly in children older than 24 months of age.

In a retrospective review of the records of 32 pregnant women treated for cholera of less than 24-hour duration, dehydration was moderate in 62.5% and severe in 37.5%.<sup>21</sup> Two fetal deaths occurred among the patients with severe dehydration, one on arrival and one within 8 hours of emergency room care. This series underscored the immediate favorable outcome for mother and fetus of prompt and vigorous hydration. This was accomplished initially intravenously and after 4 hours orally using the WHO oral rehydration solution (ORS). In another Peruvian series from a university hospital, of 8690 patients with cholera treated, 84 (0.96%) were pregnant women.<sup>22</sup> Eighty-one were treated using a standard rehydration protocol, 20 required hospitalization because of the clinical severity of dehydration, and 64 were treated and discharged from the emergency ward to complete treatment as outpatients. In this series, fetal deaths occurred in 7.7% of first trimester pregnancies, 6.9% in second trimester pregnancies, and 3.6% during the third trimester. Younger pregnant women (<20 years) were more frequently hospitalized (50%) than older mothers and had a higher rate of fetal death associated with the disease. Remarkably, there were no maternal deaths; three patients suffered transitory renal failure that recovered without dialysis.<sup>22</sup>

Treatment for pregnant patients with cholera consists of the rapid and adequate replacement of fluids, electrolytes, and base. There is conclusive evidence that solutions may be given orally and that the WHO ORS is safe and effective for pregnant women.

The rationale for the use of antibiotics for the treatment of cholera is that the duration and volume of fluid loss can be diminished and that clearance of *V. cholerae* from the stools can be hastened. Tetracycline, doxycycline, and quinolones have many more weaknesses than strengths in pregnancy and are not recommended. Ampicillin, TMP-SMX, and erythromycin are safer and can be substituted, provided susceptibility is assured.

Oral cholera vaccines have been available outside of the United States (see Chapter 21), but there are no data on the use of any cholera vaccine during pregnancy. Intrafamilial spread occurs but does not appear to play a major role in transmission to pregnant women.

## DENGUE FEVER AND DENGUE HEMORRHAGIC FEVER

Intrauterine transmission of dengue viruses appears to be confirmed by several case reports and small series, but the exact mechanisms of transmission and the fetal pathogenesis have not been elucidated.<sup>23–27</sup> No significant increase in prevalence or in severity of the disease has been noted associated with pregnancy. The review of many small studies of women with clinical diagnosis of dengue fever during pregnancy strongly suggests that the risk of premature birth and fetal death are increased as a consequence of the disease, as are the risks of thrombocytopenia and hemorrhage for both mother and newborn.<sup>23,25,28–30</sup>

Fever is the most common presenting symptom in the mother, and when it occurs near term, the likelihood of hemorrhage is higher.<sup>23</sup> Neonates appear healthy at birth but develop symptoms after 3 to 7 days.<sup>31,32</sup> They should be thoroughly observed even if the mothers are clinically doing well. Maternal monitoring and treatment are as described for nonpregnant individuals. When cesarean section is indicated, platelet transfusions may be necessary.

## VIRAL HEPATITIS

Infection by the hepatotropic viruses designated A, B, C, D, E, and G constitutes the most common cause of jaundice during pregnancy.<sup>33</sup> Hepatitis A and B viruses are responsible for most of the cases in developing and developed countries, and documentation of infection is most common during the third trimester. The severity and prognosis of maternal acute hepatitis A, B, C, and D does not seem to be affected by pregnancy. Prematurity and perinatal death may be slightly increased, but no increase in congenital malformations, abortion, low birth weight (LBW), or intellectual disabilities has been noted. Maternal management is not altered in any major way by the coexistence of pregnancy.

### Hepatitis A

In utero transmission of hepatitis A is not recognized, and transmission by fecal contamination during delivery is rare. Infection during pregnancy or delivery does not appear to result in increased complications in the mother or increased clinical disease in the newborn.<sup>34</sup> Acute hepatitis A in the pregnant woman requires supportive care and recovery is expected; fulminant hepatitis has been observed in less than

1% of the cases. For newborn infants of infected mothers, immunoglobulin (Ig) is given as prophylaxis in postexposure situations.<sup>34</sup> Pregnant women may wish to avoid travel to endemic areas, and when nonimmune to hepatitis A, can receive immunization or Ig prophylaxis when needed.

### Hepatitis B

Hepatitis B infection is highly prevalent in the tropics, where large segments of the population are not exposed to universal vaccination programs. Areas such as sub-Saharan Africa, the Amazon basin, most Pacific islands and some Caribbean islands, parts of the Middle East, and China have the highest prevalence of hepatitis B virus (HBV) infection. High prevalence can be expected in these areas during reproductive years.

Acute hepatitis B occurs in approximately 1 to 2 per 1000 pregnancies,<sup>33</sup> and it does not seem to pose special risks to the mother when compared to background rates for the general population. However, perinatal exposure poses great risk for acquisition of HBV by the infants born to hepatitis B surface antigen (HB<sub>s</sub>Ag)–seropositive mothers. The frequency of chronic hepatitis B in pregnancy is higher (approximately 5–15 per 1000) and also constitutes a risk for vertical transmission. Data from the Centers for Disease Control and Prevention (CDC) analyzed in 1996 estimated that 22,000 children are born to HBV-positive mothers every year in the United States alone. In highly endemic areas, the risk to the neonate to become perinatally infected and to develop chronic infection is very high.<sup>35,36</sup> Therefore, all pregnant women should be screened for HB<sub>s</sub>Ag during prenatal visits. Transmission rates are higher if the mother is also hepatitis B e antigen (HB<sub>e</sub>Ag)–positive.<sup>34</sup> Intrauterine infection occurs as evidenced by the fact that 2.5% of infants born to infected mothers have hepatitis B antigenemia during the neonatal period, but in most cases antigenemia appears later, suggesting transmission at delivery. Maternal blood, amniotic fluid, or feces may contain HBV, but cesarean section delivery and avoidance of breastfeeding do not prevent transmission. Most vertically infected infants carry HB<sub>s</sub>Ag by 2 to 5 months of age, but in some detection may take longer. Up to 20% of infants born to HB<sub>s</sub>Ag-positive mothers may become infected, and up to 90% of infants infected by their HB<sub>e</sub>Ag-positive mothers may become chronically infected if untreated. Gestational age, birth weight, and viral subtype do not appear to predict the likelihood of the baby becoming a chronic carrier. Although HB<sub>s</sub>Ag has been found in breast milk, breastfeeding does not appear to be a major risk factor for transmission. Most cases of HBV infection during pregnancy are asymptomatic, and when symptomatic the illness is similar to that of the general nonpregnant population. Fulminant hepatitis B<sup>37</sup> has been described at a rate of approximately 1%.

The diagnosis and management of hepatitis B during pregnancy is similar to that of nonpregnant patients. Hepatitis B vaccination is not contraindicated during pregnancy or lactation. Women of unknown HB<sub>s</sub>Ag status who present in labor or after delivery should be considered potentially infected. Infants born to HB<sub>s</sub>Ag-positive mothers or mothers with unknown HB<sub>s</sub>Ag status must receive monovalent hepatitis B vaccine along with 0.5 mL of hepatitis B immunoglobulin (HBIG) at a different anatomical site within 12 hours of birth,

and complete a total of four or five doses regardless of gestational age.<sup>38</sup> The series can be completed using combination vaccines. Adoptees should be tested for HB<sub>s</sub>Ag. All children must be vaccinated. Postvaccination testing and revaccination are beyond the scope of this chapter but have been recently investigated.<sup>39</sup>

The management of hepatitis D coinfection during pregnancy does not differ from the management of hepatitis B. Perinatal transmission has been reported. Neonatal prophylaxis as described for HBV may prevent transmission of HDV.

### Hepatitis C

A major problem worldwide, infection with the hepatitis C virus (HCV) has not been shown to affect fertility or increase rates of abortion, prematurity, LBW, or obstetric interventions compared to control subjects. There is, however, a risk of transmission from mother to infant of approximately 5%. Although the risk of perinatal transmission and the severity of the maternal disease must be considered, there is no contraindication for pregnancy in HCV-infected females. Vertical transmission in utero and during birth canal passage occurs, especially when high maternal viral loads are present<sup>40</sup> and when the expectant mother is an IV drug user and or is coinfecting with HIV.<sup>41</sup> Nonviremic mothers (gravidas) rarely transmit HCV, but viremia at delivery reaches 55% to 75% rates. Current treatment options for hepatitis C such as pegylated interferon plus ribavirin are not used during pregnancy because of the unknown efficacy for treatment and prevention and the risk for potential side effects for mother and fetus. Delivery by cesarean section and avoidance of breastfeeding may decrease transmission, but data are inconclusive<sup>42</sup> and no formal evidence-based recommendation can be given at this time. Routine screening of all pregnant women is not recommended. Testing can be recommended for high-risk women and their offspring and for potential adoptees. Anti-HCV antibodies are usually present by age 1 year and PCR can detect HCV earlier.

### Hepatitis E

There are data that suggest that infection with the hepatitis E virus (HEV), found most commonly in endemic areas of the Indian subcontinent, the Middle East, Southeast Asia, and Latin America, can be associated with higher mortality from fulminant disease during pregnancy,<sup>43</sup> especially when acute disease develops in the third trimester. Intrauterine death has been associated with severe disease and hypoglycemia. Perinatal transmission may occur more commonly than initially estimated<sup>44</sup> and may cause infant mortality as well. Immunoglobulin pooled from patients in endemic areas may prove beneficial.

### Hepatitis G

In HIV-1-infected women, hepatitis G virus (HGV) coinfection is common,<sup>45</sup> and HGV can be transmitted sexually. Children born to HGV RNA-positive women coinfecting with HIV are also likely to be HGV infected. Transmission appears to occur antenatally. Children remain infected and asymptomatic for long periods.

## HUMAN IMMUNODEFICIENCY VIRUS AND ACQUIRED IMMUNODEFICIENCY SYNDROME

Globally, women represent approximately 60% of the total population of human immunodeficiency virus (HIV)-infected individuals, and the more efficient heterosexual, male-to-female transmission constitutes their greatest exposure risk. Younger women have the highest risk of infection. In areas of sub-Saharan Africa, HIV infection rates in pregnant women may exceed a staggering 25%. The disparity in the delivery of interventions to halt the deleterious effects of HIV and acquired immunodeficiency syndrome (AIDS) between developed and developing countries is very large and growing.

HIV infection is transmitted from an infected mother to her fetus during pregnancy, during delivery, and by breastfeeding. The timing of infection has been estimated and is schematically represented and simplified in Table 136-3. Determinants of transmission efficiency include social factors, concurrent sexually transmitted diseases (STDs), CD4 count and viral load, antiretroviral therapy (ART), as well as obstetric factors and feeding choices. Currently, with the vanishing exception of a few surviving children infected by blood products decades ago, virtually all HIV infections in children less than 13 years of age have been transmitted vertically from their infected mothers. In the United States alone, approximately 7000 HIV-positive women give birth each year. Worldwide, the number of HIV-infected mothers delivering infants is increasing dramatically, mainly in developing areas, while a major decrease has been noted in industrial countries.

Given no comorbidities, and accepting imperfections in the published studies, HIV infection appears to have little if any effect on pregnancy and pregnancy has little if any effect on HIV disease progression. Anemia, LBW, and prolonged labor are more frequently reported from areas where women have more advanced or untreated disease, malnutrition, and coinfections, but pregnancy does not adversely influence survival except in women with very advanced disease.<sup>46,47</sup>

Recurrent vaginal candidiasis is a common presenting complaint during pregnancy in HIV-infected women. With the exception of Kaposi's sarcoma, more common in men, the rates and patterns of symptoms, opportunistic infections, and malignancies are similar in nonpregnant and pregnant women. A somewhat greater predisposition to suffer esophageal candidiasis and bacterial pneumonia has been suggested in the literature. The diagnosis of HIV infection during pregnancy

**Table 136-3** Timing of HIV Transmission from Mother to Infant (n = 100)

Gestational Age (in weeks)	Number Infected
≤14	1
14–36	4
36–labor	12
Intrapartum	8
Breastfeeding	Variable
Total developed countries	14–32%
Total developing countries	25–48%

Modified from Kourtis AP, Bulterys M, Nesheim SR, et al: Understanding the timing of HIV infection from mother to infant. JAMA 285:709–712, 2001 and several other authors.

is made in the same manner as in nonpregnant females. Shortcomings of the use of ELISA and Western blot tests in pregnant women must be kept in mind. Once diagnosed, a number of interventions to prevent or minimize mother-to-child transmission of HIV become vitally important. In the United States, aiming at the maintenance of the health of the patient and at interventions that sharply reduce vertical transmission, published guidelines recommend voluntary counseling and HIV testing to all pregnant women as early in pregnancy as possible.<sup>48</sup> Counseling must be based on testing that provides definitive information. In the developing world, in many areas of Africa, Asia, India, Latin America, and the Caribbean, very large numbers of pregnant women do not recognize the need for prenatal care, have difficulties accessing health facilities and personnel, and receive no or suboptimal diagnostic, prophylactic, and therapeutic interventions. This situation must change. Expert monitoring for health maintenance during pregnancy and for HIV-related issues must be assured. HIV-related monitoring must include timely testing, the prevention and treatment of opportunistic infections including tuberculosis, the use of pregnancy-specific individualized combination ART,<sup>49</sup> the timely election (or not) of the cesarean section, and discouraging (or not) of breastfeeding. These are all desirable, but not always or seldom possible in poor regions.

Current criteria for recommendation of combination ART in females in general apply to pregnant women. During pregnancy, individualization becomes more important and decisions about the initiation, continuation, and choice of treatment include fetal factors. Combination ART offers greater protection against perinatal transmission and should be considered even if the mother does not fulfill criteria for initiation of ART. Zidovudine (ZDV) should be included when possible. A single dose of nevirapine to mothers with HIV, when added to oral ZDV, has recently been proven highly efficacious in reducing vertical transmission of HIV,<sup>50</sup> but resistance mutations may appear in mother and baby.<sup>51</sup> In pregnant HIV-positive women, reverse transcriptase inhibitors (RTIs) may be responsible for more frequent and pronounced lactic acidosis and even hepatic steatosis. Protease inhibitors (PIs) may worsen insulin resistance and hyperglycemia. Hemolysis, elevated liver function tests, and low platelets, the so-called HELLP syndrome described in late pregnancy in otherwise healthy HIV-infected women, may also be more common with use of RTIs and PIs. Efavirenz is contraindicated in pregnancy because of simian embryopathy. Stavudine and dideoxyinosine (ddI) in combination with either PIs or nevirapine must be avoided or discontinued in pregnancy. An Antiretroviral Pregnancy Registry ([www.apregistry.com](http://www.apregistry.com)) has been designed to better understand the strengths and weaknesses of the use of ART during pregnancy and may become an important international tool.

Elective cesarean section reduces the risk of perinatal transmission of HIV even in women who are taking antiretroviral drugs and even at low maternal viral loads,<sup>52</sup> but maternal morbidity is a consideration. With undetectable maternal viral loads, no evidence exists to guide a recommendation at this time.<sup>53</sup> Breastfeeding is discouraged in areas where infant formula is available, but extremely controversial in poor parts of the world where over 95% of HIV-infected women reside<sup>54</sup> who for social, economic, and other reasons will continue to lactate.

To control HIV infection and AIDS in women, pregnant women, and children, major global efforts will be required that close the growing standard of care gap between rich and poor and to ensure that the huge medical advances of the last decades reach as many people as possible.

## HUMAN T-LYMPHOTROPIC VIRUS TYPE I

Human T-lymphotropic virus type 1 (HTLV-I) infection, a frequently ignored but important disease, is hyperendemic in the south of Japan and endemic in Africa, the Caribbean, and Latin America. Based on small studies, the clinical course of pregnancy does not seem to be altered by the presence of infection by HTLV-I and babies appear normal at birth. Vertical transmission does occur in 6% to 35% of newborns, usually postpartum via breast milk.<sup>55</sup> There is a threefold increased risk of transmission with breastfeeding for more than 6 months; from less than 10% to almost 35%. When breastfeeding was continued for more than one year, the proportion of infected children rose to almost 40% (E. Gotuzzo, unpublished data, 2005). Mothers with strongyloidiasis seem to transmit HTLV-I with enhanced efficiency, in contrast with asymptomatic mothers or those suffering tropical spastic paraparesis. Intrauterine and intrapartum transmissions also occur, but together they account for approximately 5% of vertical transmission. Perinatally transmitted HTLV-I infection poses a risk for the development of adult T-cell leukemia/lymphoma.<sup>56</sup>

Routine combination HTLV-I/II antibody testing of blood products is a strategy implemented in the United States since 1997, and in countries where the prevalence of infection in pregnant women exceeds 2% to 4%, screening of all pregnant mothers and formula feeding of infants of infected mothers is a logical strategy that is in use in Japan.<sup>57</sup> It may reduce childhood infection rates by nearly 90% and is a strategy that requires further study in less developed tropical countries. There is no therapy or vaccine available.

## LEPTOSPIROSIS

*Leptospira* survives well in tropical nonsaline waters and leptospirosis is common in several tropical settings.<sup>58,59</sup> In certain endemic areas, up to 5% to 10% of patients who present to academic or research institutions may have leptospirosis. Data about leptospirosis occurring during gestation are scarce and come from small case series and reviews, case reports, and anecdotal information.<sup>60-65</sup> Little is known about the mutual effects of pregnancy and leptospirosis when they coincide in the same woman. Transplacental transmission is thought to occur and leptospira have been found in infected organs of mother and fetus. In a series of 11 cases diagnosed by culture or serology in French Guyana, fetal death occurred in over 50% of the cases.<sup>64</sup> In another report of one case from Israel and a review of 15 previous cases, eight pregnancies terminated in abortions, four newborns had neonatal leptospirosis and four were uninfected and appeared normal at birth.<sup>61</sup> During the early months of pregnancy, leptospirosis is more likely to result in spontaneous abortion, and during the last trimesters, more premature deliveries and neonatal disease result. Leptospirosis may present with jaundice and pulmonary abnormalities in a higher percentage of pregnant than nonpregnant women but these observations have not

been confirmed.<sup>60</sup> Maternal mortality seems not affected compared to the background of nonpregnant women. Early diagnosis and antibiotic treatment of leptospirosis during pregnancy is essential. High-dose penicillin or ceftriaxone is associated with faster maternal recovery and improved fetal prognosis. Doxycycline is contraindicated during pregnancy. The Jarisch–Herxheimer reaction occurs rarely.<sup>66</sup>

## LISTERIOSIS

Pregnancy is a risk factor for infection with *Listeria monocytogenes*.<sup>67</sup> Listeriosis among pregnant patients mainly affects women who have no comorbidities; cell-mediated immunity depression attributed to pregnancy itself has been cited as a predisposing factor. The incidence of listeriosis is estimated to increase from approximately 0.7 per 100,000 in the general population to approximately 12 per 100,000 in pregnant women, and intrauterine infection has been clearly associated with placental colonization, chorioamnionitis, spontaneous abortion, stillbirth, preterm labor, prematurity, and neonatal infection (including granulomatosis infantiseptica) and significant mortality.<sup>67,68</sup> In humans, there are no convincing data to link the past history of listeriosis with repeated spontaneous abortions.

Maternal infection, which can occur at any gestational age, presents clinically as a mild to moderate febrile illness, but a flulike syndrome is also a common presentation.<sup>67</sup> Maternal infection can occasionally be severe and meningitis has been reported. A high index of suspicion is essential to obtain specimens for microbiological confirmation of diagnosis. Specimens that are useful for culture of the organisms include maternal blood, placenta, amniotic fluid, cervical secretions, stool, and urine. Blood cultures should be performed to evaluate fever and/or flulike symptoms in pregnant women because they can detect the organism in some 35% of the cases. Gram stains of the placenta, as well as frozen sections when available, can produce a rapid presumptive diagnosis.

Early gestational listeriosis may result in bacteremia and seeding of the uterine contents. Fetal prognosis, worse in early pregnancy, is guarded throughout. Treatment of the disease at early stages is associated with better pregnancy outcomes. Approximately 20% of pregnancies complicated with listeriosis result in fetal death, and approximately two-thirds of the surviving infants develop neonatal disease. Early-onset neonatal listeriosis (<5 days) is predominantly septic and with correct treatment carries a high (approximately 30%) mortality rate; late onset (>5 days) is predominantly meningitic and mortality is lower (approximately 10%) with therapy.<sup>69</sup> A common differential diagnosis is with group B streptococcal sepsis. Disseminated neonatal disease is extremely serious and, if associated with prematurity, has a mortality rate that may approach 90%. Neurologic sequelae have been reported in survivors of neonatal disease. Furthermore, even neonates who do not develop clinically apparent listeriosis but who are born to mothers who suffered listeriosis during their pregnancy may have prolonged hospital stays.

During pregnancy, high-dose ampicillin, considered superior to penicillin for this indication, is felt to be the treatment of choice; adding gentamicin is synergistic and its use must be evaluated in special situations in light of the potential side

effects to the fetus. Cephalosporins and clindamycin are not effective. No risk-free alternative exists during pregnancy and when penicillin hypersensitivity is suspected or reported, allergy testing and/or desensitization should be considered. TMP-SMX, active against listeriosis but avoided during pregnancy, may—as is the case with brucellosis—offer benefits that exceed risks in certain cases. Prevention of listeriosis during pregnancy relies on the same principles that prevent listeriosis in general. They should be stressed as most important for women of reproductive capacity and risk factors during pregnancy.<sup>70</sup>

## MALARIA

Malaria, the most significant parasitic disease worldwide, remains a major cause of maternal morbidity and mortality.<sup>71</sup> Globally, the pathological effects of infection during gestation and the negative implications for fetal development and survival are underscored by the fact that about 40% of the world's pregnant women (approximately 1 billion) are exposed to the risks of malaria while pregnant. LBW, a common consequence of gestational malaria, is an important risk factor for infant and childhood mortality.<sup>72</sup> In Africa alone, malaria-induced LBW may kill nearly 400,000 infants each year. Recent studies have demonstrated that the frequency and severity of placental malaria and consequential newborn disease and LBW are greater in pregnant women with concomitant HIV infection.

The negative impact of plasmodial infection during pregnancy varies predictably according to maternal immunity, a consequence of the intensity of transmission, and the parasite species. In areas of unstable transmission, where malaria is uncommon except during epidemics and immunity is rare, pregnant women suffer high-level parasitemia with more severe, acute complications including anemia, hypoglycemia, pulmonary edema, the acute respiratory distress syndrome, cerebral malaria, and death. Fetal distress, premature labor, stillbirth, or LBW result.<sup>73</sup> Fetal and perinatal losses have been estimated to be as high as 60% to 70% in nonimmune pregnant woman. This situation is similar in pregnant women from nonendemic areas or travelers to malarious zones. In contrast, adults who are long-term residents of areas of moderate or high malaria transmission exhibit high-level immunity and infection is usually asymptomatic or mild. But during gestation, this immunity is altered. Infection is still frequently oligo- or asymptomatic and severe disease is uncommon,<sup>73</sup> but it is associated with accumulation of parasitized erythrocytes in the placental microcirculation. In these areas, up to three doses of presumptive intermittent treatment during the duration of gestation has been shown to decrease the risk of severe maternal anemia. Sequestration of *Plasmodium falciparum*-infected red blood cells in the placenta is due to parasite adhesion molecules expressed on the surface of erythrocytes binding to host receptors such as chondroitin sulfate A (CSA). Parasite ligands also mediate placental adhesion. Thus, by invading the placenta,<sup>74</sup> malaria parasites cause more severe maternal anemia and LBW babies. These complications tend to be more common in primi- and secundigravida women with *P. falciparum* infection (weight reduction, approximately 170 g) and in multigravida women with *P. vivax* infection (weight reduction, approximately 100 g).

Congenital malaria is acquired from the infected, usually nonimmune mother pre- or perinatally in less than 5% of newborns. The transmission efficacy and the clinical severity are functions of the parasite species (more commonly observed with *P. vivax* and *P. malariae* but possible with all human plasmodia) and their density in maternal blood and placenta. In fact, placental malaria is significantly associated with stillbirth regardless of parity. A serious problem in tropical areas, it is rarely reported in the United States. Congenital infection is an important cause of intrauterine growth retardation, premature birth, abortion, miscarriage, stillbirth, and neonatal and infant death. The clinical manifestations can be apparent from the first day after birth to about 1 month later (commonly 10–30 days). They include fever, restlessness, pallor, obtundation, poor feeding, diarrhea, and vomiting. Signs include jaundice, cyanosis, and hepatosplenomegaly. Hypoglycemia is associated with increased mortality and neurologic sequelae.

The clinical features of malaria in obstetric patients, including laboratory and image findings, can be quantitatively more severe and qualitatively unique, but are essentially the same as described in detail for nonpregnant individuals.<sup>75</sup> Features indicating a poor prognosis must always be investigated. Special attention to physical exam, including level of consciousness, blood pressure, urine output, hemoglobinuria, hemoglobin and hematocrit, leukocytes, coagulation tests, arterial blood gases and blood glucose and lactate levels, creatinine, aminotransferases, bilirubin, muscle enzymes, and urate levels as well as chest radiography, is warranted. In serious cases, this is best done in intensive care unit (ICU) settings until clinical stability/improvement. An HIV test is commonly indicated.

Early diagnosis of malaria in pregnancy is extremely important because successful specific treatment can impact mother and child. The diagnosis rests, as in nonpregnant individuals, on the demonstration of asexual plasmodial forms in thick and thin stained smears of peripheral blood. Fluorescent microscopy, rapid detection tests, and polymerase chain reaction (PCR) are described in Chapter 90. Parasitemias can be very high. Serology has mainly epidemiological uses.

Malaria during pregnancy must be treated with antiparasitic agents, but optimal therapy is difficult to select because there are no reliable clinical data for most oral or parenteral antimalarial drugs to be declared safe for use in pregnant women. The agent or agents of choice and the route of administration also depend on the suspected or demonstrated infecting species and the likelihood of drug resistance. The geographic distribution of drug-resistant malaria parasites can be found elsewhere in this book. Antimalarials with special importance during pregnancy are briefly described here and their administration schedules are found in Chapter 90; drug doses may need to be altered depending on the stage of pregnancy. In pregnancy, the persistence of *P. falciparum* in the placenta after apparently effective treatment has been described.<sup>76</sup>

Chloroquine is generally well tolerated and considered safe in pregnancy<sup>77</sup> and continues to be the drug of choice for all *P. ovale* and *P. malariae* infections and for susceptible *P. falciparum* and *P. vivax* infections.

With the exception of the possibility of stillbirth and LBW, mefloquine, used for treatment and prophylaxis, appears safer for the fetus during any trimester of pregnancy than many other drugs and has been used extensively.<sup>78</sup> In the expectant

mother, the drug may produce neuropsychiatric side effects and possibly cardiotoxicity. Combination with halofantrine, not available in the United States, produces prolongation of QTc interval. Tetracyclines and doxycycline are contraindicated during pregnancy; clindamycin (see later discussion) is an alternative. Dapsone in combination with other drugs might provide an alternative to treatment of resistant *P. falciparum* malaria, as suggested by a recent review of 924 pregnancies,<sup>79</sup> but there is no information on hemolytic effects to mother or fetus with or without glucose-6-phosphate dehydrogenase (G6PD) deficiency.

The combination of atovaquone (250 mg) and proguanil (100 mg) is highly effective against chloroquine- and mefloquine-resistant *P. falciparum* malaria, but data in pregnancy are scarce. Combined with artesunate, the combination has been useful and well tolerated in Thailand<sup>80</sup> as rescue treatment of multidrug-resistant *P. falciparum* malaria in pregnant women without recorded maternal or fetal toxicity.

Quinine and quinidine have been given in therapeutic doses to pregnant women throughout gestation<sup>77</sup>; continuous monitoring of vital signs, blood glucose, and EKG are recommended. Quinine is preferred but availability accounts for greater use of quinidine in North America. Quinine at the intravenous doses used to treat malaria does not induce oxytocic effects. There are concerns about maternal cardiac side effects and tolerance, especially gastrointestinal.

Pyrimethamine-sulfadoxine and clindamycin have also been used in pregnancy with consistent good results; fears of development of kernicterus with the former and colitis with the latter have not materialized. Clindamycin has been used routinely in combination with quinine to treat pregnant patients with multidrug-resistant *P. falciparum* in Brazil for two decades; other than vomiting, no significant side effects have been observed in mothers or fetuses. It should not be used alone because of its slow antimalarial activity.

Artemisinin-derived antimalarials and combinations have considerably faster parasitic clearance rates and shorter half-lives and may be as effective as quinine in treating severe malaria. They can be used orally, intravenously, and rectally. Small studies suggest good tolerance during pregnancy and no evidence of adverse fetal effects.<sup>80</sup> Birth outcomes are similar to community rates for abortion, stillbirth, and congenital anomalies or mean gestation age at delivery. There is a risk of potential teratogenicity if used in the first trimester.

The use of intravenous antimalarials in combination with exchange transfusions with careful monitoring should be considered in selected cases of severe complicated malaria in pregnant women.

We recommend hospitalization for pregnant women with suspected malaria at lower levels of severity than for nonpregnant counterparts. This is true for ward and ICU admission. When *P. falciparum* is suspected or demonstrated, or when disease is moderate to severe, hospitalization is always strongly recommended. *P. falciparum* treatment is administered when the organism is demonstrated or suspected (even if not demonstrated) for all infections where one suspects infection with more than one organism, and for severely ill patients.

Chloroquine alone, or with proguanil, remains the preferred drug for chemoprophylaxis for pregnant women in malarial areas where it is still effective. In chloroquine-resistant areas, mefloquine may be used instead.

Doxycycline, atovaquone-proguanil, and primaquine are not used for prophylaxis. Intermittent preventive treatment (IPT) with pyrimethamine-sulfadoxine in areas of parasite susceptibility is a common option. Recently, the use of a double dose was associated with a decrease of maternal parasitemia and newborns with malaria, among nulliparous and primiparous pregnant women in Mozambique. The safety of other prophylactic agents has not been established. Pregnant women from nonmalarial areas should not visit malarial zones, but when unavoidable, antivector strategies cannot be overemphasized.

Women become resistant to pregnancy-associated malaria over successive pregnancies as they acquire antibodies that recognize placental parasites, suggesting that protection by a vaccine during pregnancy is feasible.

## TETANUS

Maternal tetanus is an extremely serious disease with high morbidity and mortality. It is not communicable, but may be acquired by ways unrelated to pregnancy, such as dirty wounds, or pregnancy-related, such as contaminated delivery or abortion. Tetanus neonatorum, the most common form of tetanus in developing tropical countries, is caused by contamination of the umbilical stump with spores, typically from application of animal dung to the umbilical stump. Virtually all affected are not properly immunized. Symptoms develop after 3 to 14 days. Even with specific treatment, maternal and neonatal tetanus have high mortality rates.

The clinical picture in mother and infant is secondary to the potent tetanospasmin exotoxin produced during anaerobic growth of *Clostridium tetani* at the site of injury and has been described elsewhere. The diagnosis is clinical, and aggressive treatment, performed in intensive care settings, includes life-sustaining methods, sedation, passive and active immunization, and antibiotics. Tetanus is preventable with the use of one of the safest available immunization products. Immunization of the susceptible pregnant woman should be routine<sup>81,82</sup> and include at least two doses of tetanus toxoid, 4 to 8 weeks apart, at least two 2 before delivery. A booster is indicated for pregnant women immunized more than 10 years previously. Partially immunized women should complete a three-dose series. Clean practices for caring for the umbilical stump are clearly to be enforced.

## TOXOPLASMOSIS

The incidence of toxoplasmosis during pregnancy is estimated to be similar to that of nonpregnant women of the same age group, and most infections are asymptomatic. A minority of infected patients, calculated around 20%, develops clinical signs and symptoms of a usually self-limited and rarely prolonged disease.<sup>83</sup> The diagnosis may be made at consultation with symptoms or when specific serological tests are performed after conception.

When infection by *Toxoplasma gondii* is acquired by a woman near the time of conception or during gestation,<sup>84</sup> the organism may be transmitted to the fetus through the placenta. This happens in about one-third of the cases. The incidence of congenital toxoplasmosis in the United States is estimated in 1/1000 to 1/8000 live births or 400 to 4000 infants per year.

The parasite reaches the placenta after hematogenous spread of tachyzoites released from ingested cysts or oocysts after release of bradyzoites or sporozoites that have invaded the maternal intestinal epithelium. In placental tissue, tachyzoites (demonstrated by Wright, Giemsa, and immunoperoxidase) replicate and cause tissue damage evidenced by chronic inflammation and cysts. From the placenta, hematogenous spread and establishment of a persistent infection with potential for lifelong reactivation and further disease occurs in the fetus.

Before conception, the likelihood of vertical transmission increases from about 6 months to the establishment of pregnancy. Once established, the age of gestation at the time of infection is a critical factor in transmission and fetal outcome. Infections occurring during the first trimester have the lowest vertical transmission (approximately 15%), but the resulting neonatal disease is more severe. The presence of HLA-DQ3 can worsen the prognosis of the fetus when infected in this period. During the third trimester, transmission is greatest (approximately 65%), but clinically apparent neonatal disease is less common or severe. The differences may be explained by placental or immunologic factors.

In severe prenatal infections, intrauterine fetal death may be the consequence of fetal multiorgan failure secondary to parasitic invasion. Acute congenital toxoplasmosis is characterized by intrauterine growth retardation and prematurity, anemia, thrombocytopenia and jaundice, hepatosplenomegaly, hydrocephalus, microcephaly, and intracranial calcifications. Surviving congenitally infected babies, including untreated asymptomatic neonates, most often exhibit neurological sequelae such as chorioretinitis (and visual impairment), seizures, and learning disabilities later in childhood and by adolescence.<sup>83,85-87</sup> Clinical manifestations are often similar in monozygotic and different in dizygotic twins. In the latter instance, diagnosis of severe toxoplasmosis in one twin can suggest subclinical disease in the other. Early and appropriate treatment may allow for clinical cure and normal development and is of critical importance.

When clinical manifestations of toxoplasmosis in the pregnant woman become apparent, they do not differ from those described for immune competent nonpregnant individuals. Single or multiple, usually nontender cervical lymphadenopathy<sup>88</sup>; nonspecific flulike symptoms such as headache, malaise, fatigue, fever, sore throat, abdominal discomfort, and pain; a maculopapular rash; and meningoencephalitis have been well described. More rarely, lung, pericardium and myocardium, brain, and striated muscles can be affected.

The efficient diagnosis of toxoplasmosis during pregnancy can be extremely challenging. In practice, serologic tests are the most commonly used, but they require experience to be interpreted correctly.<sup>83</sup> Acute *Toxoplasma* infection can be diagnosed by the isolation of the parasite in blood or body fluid cultures from the mother and any fluid or tissue from the fetus or neonate. Immediate intraperitoneal inoculation of processed blood, body fluids, or tissues into mice, and periodic examination of mouse peritoneal fluid looking for tachyzoites, takes several days; examination of surviving inoculated mice with detectable antibody for brain cysts takes about 6 weeks. Reinoculation of mouse tissues into other mice is even more cumbersome and time consuming. Thus, cultures are difficult and expensive and, in pregnancy, may not provide a useful window of diagnostic opportunity.

In a pregnant woman with lymphadenopathy, characteristic histological features can support a clinical diagnosis of acute toxoplasmosis.<sup>88</sup> Histologic and histochemical examination of biopsy specimens, bone marrow aspirates, cerebrospinal fluid (CSF), amniotic fluid, and other specimens is rarely performed during pregnancy but can demonstrate tachyzoites. More than one staining method (including immunoperoxidase) is necessary. In the mother, tissue cysts are diagnostic, but the duration of infection cannot be ascertained. Cysts in the placenta or fetal/newborn tissues represent congenital infection.

In broad terms, recent *Toxoplasma* infection can be diagnosed by the presence of *Toxoplasma*-specific IgM antibody, by the simultaneous presence of specific IgM and IgG antibodies, or by demonstration of seroconversion of repeated IgG antibody titers. The presence of IgA antibodies suggests recent infection. A wide range of serologic tests is available commercially, and experience with their utilization varies among laboratories and societies. Systematic serologic screening of all women preconception, during pregnancy, and intra-partum is strongly advised, but in tropical countries this is seldom performed.

IgM-based diagnosis is based on the rapid—few days—rise and fall—weeks to months—of antibodies. It includes the utilization of the IgM indirect fluorescent antibody (IgM-IFA) test, the double-sandwich enzyme-linked immunosorbent assay (ELISA), and the immunosorbent agglutination assay (ISAGA). All tests are sensitive and specific. The ELISA is more sensitive and specific than the IgM-IFA test, circumvents the false positive results from rheumatoid factor in the mother and the false negative results from transferred maternal IgG in the newborn, and has been used to detect infection in pregnant women. The ISAGA avoids false-positive results from the presence of rheumatoid factor and antinuclear antibodies. ISAGA IgM is detected earlier, with higher sensitivity, and for a longer time than with the ELISA test. An IgA ELISA is even more sensitive for detection of acute infection in some pregnant women and congenital infection in newborns, but may remain elevated for months to years. A simple, accurate, and inexpensive French agglutination test is available in Europe.

IgG titers can be detected in low levels as early as 1 to 2 weeks after infection, peak with high titers ( $\geq 1:1000$ ) after 6 to 8 weeks, and decline to a new individual low level (1:4–1:64) to persist for life. The Sabin-Feldman dye test, the IgG-IFA, and the ELISA are sensitive and specific and have been in sustained clinical use.

Other serology-based diagnostics include the differential agglutination (HS/SC) test, which may be especially useful to exclude remote infection in pregnant women, the avidity test, and the indirect hemagglutination test (IHA). The IHA should not be relied upon for diagnosis of acute infection during pregnancy because it may remain negative for a prolonged period after infection.

During the acute phase of toxoplasmosis during pregnancy, antigen present in serum samples can be detected by PCR. PCR performed in amniotic fluid is the diagnostic test of choice for congenital fetal infection.<sup>89,90</sup> Timing at 18 weeks of pregnancy is preferred because of optimal sensitivity. A reference laboratory should confirm the diagnosis of acute toxoplasmosis during pregnancy.

Ultrasonography is also useful for fetal diagnosis. Combined with amniocentesis for PCR, a sensitivity of 97% and specificity of 100% for fetal infection is reached.

Appropriate treatment of a woman who acquires *Toxoplasma* infection during pregnancy<sup>84</sup> has been shown to reduce placental invasion and prevent congenital infection of the fetus carried in that pregnancy. Spiramycin (1 g taken every 8 hours by mouth on an empty stomach) is started as soon as possible<sup>87</sup> to prevent fetal infection, because it decreases vertical transmission (from approximately 60% to approximately 20%). When fetal infection seems highly probable or severe and when diagnosis of fetal infection is certain, combination therapy with pyrimethamine (50 mg PO once daily) and sulfadoxine (2 g PO twice daily) are given with folinic acid (10 mg PO once daily). During the first trimester, when pyrimethamine can be teratogenic, spiramycin is substituted and no folinic acid is needed.

No treatment is needed in subsequent pregnancies or for infections acquired over 6 months before any conception provided maternal immunocompetence, but previously infected immunosuppressed women should be given spiramycin for the duration of each pregnancy. In pregnant HIV-infected women, as a reasonable, albeit theoretical approach, spiramycin can be used for the first 17 weeks of gestation followed by pyrimethamine (at a higher dose of 75 mg PO once daily), sulfadoxine, and folinic acid until delivery. Clindamycin (1.2 g IV every 6 hours) can be used instead of sulfadoxine.

There is no *Toxoplasma* vaccine. Women who do not exhibit specific antibodies against *T. gondii* must be counseled. Avoiding raw meats and contact with cat excreta have proven preventive efficacy. All women not previously tested must have serologic screening at the first prenatal visit and during delivery.

## TUBERCULOSIS AND MULTIDRUG-RESISTANT TUBERCULOSIS

The increasing burden of tuberculosis (TB) during pregnancy affects the health of large numbers of mothers and infants.<sup>91</sup> Diagnostic, therapeutic, and prophylactic constraints during gestation include the dangers of x-rays and the intrinsic difficulties in testing anti-TB drugs.

Untreated pulmonary and particularly extrapulmonary TB (other than lymphadenitis) in pregnant women increase the risk for prematurity, fetal growth retardation, LBW, and perinatal mortality.<sup>92,93</sup> The most common mechanism of infection in the newborn is airborne transmission from an adult with pulmonary TB. Congenital TB is rare. It is more likely to be transmitted vertically after primary infection than after reactivation of previous infection. It may occur from a placental lesion through the umbilical vein, from which bacilli reach the fetal liver where a primary focus may be established for hematogenous spread to several organs. In the lungs, oxygenation and pulmonary circulation after birth increase and activate dormant bacilli. A less frequent mechanism is aspiration of infected amniotic fluid. Newborns show signs of TB after the second postnatal week; these are nonspecific and resemble other forms of neonatal sepsis. Fever, respiratory distress, irritability, ear discharge, abdominal symptoms, pulmonary infiltrates, and hilar or generalized lymphadenopathy are common. Up to 50% of infants develop meningitis. Frequently, the mother's disease is discovered as a consequence of the diagnosis in the newborn. The infant's purified protein derivative (PPD) becomes positive after 1 to 3 months. *M. tuberculosis*

can be isolated from middle ear drainage, bone marrow, tracheal aspirate, and liver biopsy, rarely from CSF. Mortality is high with delayed diagnosis.

Because untreated TB is harmful to both the mother and the fetus, because it represents a great danger to the infant after delivery, and because the disease can be transmitted to others, TB in pregnant women always should be treated without delay. Consensus treatment guidelines have been produced by the American Thoracic Society (ATS), the Infectious Diseases Society of America (IDSA), the CDC,<sup>94</sup> WHO,<sup>95</sup> and the International Union against Tuberculosis and Lung Diseases (IUATLD).<sup>96</sup> The following discussion on anti-TB drug use by pregnant women will closely follow the guidelines. Dosages are individualized during pregnancy and a general discussion can be found in Chapter 36.

The initial regimen, provided no multidrug resistance (MDR) is suspected, consists of isoniazid (INH), rifampin (RIF), and ethambutol (EMB) for a minimum duration of 9 months and with pyridoxine. INH, RIF, and EMB cross the placental barrier but have elicited no teratogenicity.<sup>97</sup> Streptomycin should not be substituted for EMB because it interferes with the development of the ear and hearing loss or vestibular defects may affect the developing fetus (approximately 1–3 per 6 live births) at any period throughout gestation.<sup>98</sup> Presumably, other aminoglycosides such as kanamycin, amikacin, and capreomycin share the ototoxicity potential. The safety of pyrazinamide in pregnancy has not been established and the drug is not recommended for routine use in the United States. Pyrazinamide is listed among the recommendations of the WHO<sup>95</sup> and the IUATLD<sup>96</sup> and has been used without reported adverse events by some public health jurisdictions in the United States. Para-aminosalicylic acid (PAS) was frequently used in combination with isoniazid (INH); no indication of teratogenicity was encountered in children of women who used them during pregnancy. The safety of cycloserine and ethionamide is untested; one report suggested human teratogenicity from ethionamide,<sup>99</sup> a drug that causes birth defects and spontaneous abortion when used in high doses in animals. The fluoroquinolones are avoided in pregnancy because of animal teratogenicity, but may need to be used during pregnancy for treatment of MDR TB infections unresponsive to other drugs.<sup>97</sup> Levofloxacin has been used more often than moxifloxacin for treatment of adults and children, and switching from levofloxacin to moxifloxacin, which may be more active against *M. tuberculosis*, after delivery seems an appropriate option. When anti-TB drugs are to be used during pregnancy, the expectant mother should be counseled concerning the known and unknown risks to the developing fetus of all treatment offered.

High-risk or symptomatic pregnant mothers should be tested with a tuberculin skin test. The PPD or “Mantoux” (5TU) tuberculin test is the most specific and sensitive standardized screening skin test for TB and is preferred. Pregnancy does not measurably affect the response of PPD and there has been no observed evidence of adverse events on women or their children from skin testing. All pregnant women not known previously to be skin reactors and many women of reproductive capacity and high risk (symptomatic, exposed, HIV, diabetes, high prevalence, caretaker, etc.) should ideally be tested.<sup>100</sup> Subsequent investigation of skin reactors facilitates the identification of infected individuals and the treatment of tuberculosis.

Although INH is not teratogenic, the treatment of latent TB infection (LTBI) is often deferred until after delivery, when there may be an increased risk of disease, because of concerns of isoniazid-associated hepatitis, which could be more frequent and/or severe during pregnancy. There might be an exception for pregnant women who have been infected recently; INH in that situation could be started after the first trimester. Mothers with LTBI do not need to be separated from their infants after delivery and the child needs no special evaluation or treatment provided he or she remains asymptomatic. No treatment is recommended for women with inactive TB if they received adequate treatment in the past.

The diagnosis of maternal TB at delivery requires rapid and thorough evaluation of mother and child. If chest radiography and positive sputum smear confirm the diagnosis, additional steps, such as INH, skin testing follow-up, and rarely separation from the mother are necessary to protect the infant. An HIV test is also indicated.<sup>101</sup>

Because the concentrations of first-line antituberculosis drugs in human breast milk are low, breastfeeding should not be discouraged in nursing mothers treated with them.<sup>102</sup> The risk of toxicity can be minimized if the mother takes her medication after breastfeeding and substitutes saved milk or a bottle for the next feeding. The small concentrations that a baby receives during feeding are not effective as treatment for LTBI or active infection.

## TYPHOID FEVER

Studies from the early 1900s, when typhoid fever (TF) was extremely prevalent around the world, suggested an increased severity of TF when it affected pregnant women. In the pre-antibiotic era, two-thirds of pregnancies complicated by TF resulted in abortion.<sup>103</sup> In one series from the Philippines,<sup>104</sup> mortality rates were 32% and 25% as infection occurred while pregnancy progressed from the first to the third trimester, compared to an accepted general mortality rate of less than 15% to 20% for the general untreated population. Additionally, fetal prognosis was found to be quite poor, with rates around 60% for fetal demise and 35% for premature labor. Since then, small series, literature reviews, and case reports have produced contradictory reports of more severe vs. equally severe clinical manifestations of TF in pregnant women when compared to nonpregnant females. Some of the largest case series of 100 cases from Chile,<sup>105</sup> 81 cases from Mexico,<sup>106</sup> and 129 cases from Peru,<sup>107</sup> though incomplete, are consistent with the notion of increased severity of TF during pregnancy and unequivocal in showing improvement of maternal and fetal prognosis with early antibiotic treatment. They also underscore the continuous presence in tropical and subtropical areas of a disease that has been all but eradicated in societies that have achieved adequate sanitation.

*Salmonella typhi* causes sepsis of intestinal origin and colonization of reticuloendothelial tissues such as liver, spleen, lymph nodes, and bone marrow and crosses the placental barrier causing chorioamnionitis and villitis. In autopsy specimens, microscopy has revealed numerous colonies of gram-negative bacilli within the fibrin between the placental villi. Vertical transmission can also occur in late pregnancy and the perinatal period. Interestingly, cases of chorioamnionitis and transplacental and perinatal infection of a fetus by

nontyphoidal *Salmonella* strains have also been described. The neonatal disease begins after an asymptomatic period of 1 to 3 days after birth. Vomiting, diarrhea, abdominal distention, and fever are common. Seizures may occur. Anorexia and weight loss, hepatomegaly, and jaundice may be severe. Prompt treatment is effective. Maternal long-term asymptomatic carriers may pose a risk for disease in the newborn, and elimination of such state with treatment (15 of 99 in a Japanese study) may prevent infection in the newborn, but no controlled studies exist. The treatment of the carrier state in pregnancy is not known.

In the mother, prolonged fever and gastrointestinal or abdominal symptoms, at times following a nonspecific flulike prodrome, is characteristic but nonspecific for pregnancy. Rose spots, hepatosplenomegaly, and relative bradycardia are very useful when present. Gastrointestinal perforation and hemorrhage are late complications that acutely risk the lives of mother and fetus. Sustained bacteremia without endocarditis is a characteristic of typhoid fever that has three major deleterious consequences: (1) a severe activation and hyperplasia of reticuloendothelial organs, typically the intestinal and mesenteric lymph nodes, the liver, and the spleen; (2) metastatic seeding; and (3) immune complex disease. All have been described in pregnant women. Relapses and long-term carriers have also been seen in pregnancy.

*S. typhi* can be found in breast milk (5 of 26 in Chile and 3 of 23 in Peru), but treatment with amoxicillin has been effective in eradicating the organism in 1 to 3 days. Other drugs have no proof of efficacy and resistance makes this information difficult to interpret.

Whether or not TF is more severe during pregnancy, the disease must be treated to avoid morbidity and mortality in mother and fetus and to decrease transmission.<sup>105–107</sup> Currently, due to the appearance of resistance,<sup>108–110</sup> two drugs, ciprofloxacin and ceftriaxone,<sup>111</sup> are considered first-line and one, azithromycin, is considered alternative. Ciprofloxacin use in pregnancy is controversial and at present not advisable, particularly if there are alternatives, but ceftriaxone has demonstrated safety and efficacy in a series of 25 pregnant patients from French Guiana.<sup>112</sup> Provided susceptibility is assured and in spite of cost considerations, it is the drug of choice during all trimesters. Cefotaxime and cefoperazone are reasonable alternatives, but first- and second-generation cephalosporins, aminoglycosides, and aztreonam are not. Azithromycin use in pregnancy is permitted, but efficacy for treatment of TF is unknown.

Chloramphenicol is not recommended in pregnancy because of *Salmonella* resistance, the fetal risk of gray syndrome, and potential bone marrow toxicity for mother and fetus. Nevertheless, the emergence of quinolone and ceftriaxone resistance,<sup>110</sup> the possible re-emergence of susceptibility to chloramphenicol, and the absence of hematologic side effects or gray syndrome in some series, suggest a need to re-evaluate the issue.

No trials of corticosteroids in pregnancy have been performed, but their use may be justified in severe cases.

There are no data reported on the use of typhoid vaccines among pregnant women. The CDC advises to avoid vaccinating during pregnancy, but vaccination should be considered in some women (for example, those allergic to cephalosporins traveling to an endemic area) if actual risk of disease and

probable benefits of effective nonlive vaccine (such as the Vi vaccine) outweigh theoretical risks (especially the effect of live bacteria) to the fetus.

Screening with stool cultures of pregnant women seems unjustified in areas of low prevalence. In a large UK study of 30,471 mothers over 9 years, only 60 (0.2%) yielded *Salmonella*<sup>113</sup> and 43 (72%) were asymptomatic. Seven of the 60 neonates (12%) excreted *Salmonella* with similar characteristics as their mothers, but no individual suffered invasive disease. However, in other areas like Tuscany (where 7431 pregnant women were studied), stool cultures may be cost effective in late summer and fall.<sup>114</sup> In developing tropical countries, the question is unanswered. The reader is referred to Chapter 17 on TF for detailed discussions of antibiotic dosage and prevention measures.

## YELLOW FEVER

The course and severity of yellow fever do not seem affected by pregnancy, but no studies exist to confirm this assessment. Yellow fever is a very severe disease with high mortality and no specific treatment; therefore, in the general population emphasis has been placed on prevention with an easy-to-use, economical, available, safe, and very effective vaccine.

The safety of yellow fever vaccination, a live virus vaccine, has not been established during pregnancy. Studies of infants who were born to mothers that had been vaccinated with the YF17D immunogen during their pregnancies have been analyzed.<sup>115–118</sup> Infection of the fetus with the vaccine strain was documented in one newborn and no congenital abnormalities were observed.<sup>117</sup> In women vaccinated with YF17D early in pregnancy, the relative risk for spontaneous abortion was 2.3, but the difference with unvaccinated cases was not statistically significant. Seventy-four prospectively enrolled cases were analyzed; pregnancies ended in 46 births, five voluntary and seven spontaneous abortions; three newborns had minor and two major defects.<sup>115</sup> Although the samples are small, and the follow-up incomplete, these data, plus limited clinical trials in Africa and Europe, suggest that the risk of vaccination of pregnant women who are likely to be exposed to infection with the yellow fever flavivirus in endemic areas is less than the risk of contracting yellow fever. There is a theoretical but unproved risk of transmission of the YF17D strain in human milk during breastfeeding. Small studies from Brazil<sup>116</sup> and Trinidad<sup>117</sup> stress the need for caution. Therefore, pregnant and lactating women who must travel to endemic areas can be offered the vaccine with clear explanations of the risk/benefit ratio as understood at the time of consultation, if the risk of contracting yellow fever is high. Pregnant women who have been inadvertently vaccinated should be reassured. Seroconversion rates during pregnancy can be lower,<sup>118</sup> and immunity should probably be verified.

## OTHER INTRAUTERINE INFECTIONS

### Cytomegalovirus

Primary cytomegalovirus (CMV) infection during pregnancy may be transmitted to the fetus in 25% to 75% of cases. Reinfection with a different strain may have lower potential for transmission. CMV can persist in a latent stage after primary infection, and reactivate during pregnancy to be transmitted

to the fetus. Deleterious developmental outcomes have been observed in infants.<sup>119</sup> Treatment with ganciclovir has not been evaluated in pregnancy and is being studied for symptomatic congenital infection.<sup>120</sup>

## Herpes Simplex Virus 1 and 2

Genital infection by either herpes simplex virus 1 or 2 is rarely transmitted in utero to the fetus, but it is more commonly transmitted intrapartum to the newborn. It can also be transmitted later unrelated to pregnancy. Transmission occurs even in asymptomatic women, more efficiently in primary than in reactivated infections. Data on the safety of acyclovir, valacyclovir, and famciclovir are not complete but many specialists recommend its use during pregnancy in several situations.<sup>121</sup> Neonatal disease is very serious, potentially lethal, and has a high risk of severe sequelae and early treatment with intravenous acyclovir reduces but does not eliminate morbidity and mortality.<sup>114</sup> Delivery by cesarean section is advocated to prevent neonatal herpes, but this does not totally eliminate the risk.

## Rubella

Rubella remains prevalent in some areas of the developing world where vaccination programs have not reached the population. The rubella virus interferes with critical steps in fetal organ development during early pregnancy and causes the congenital rubella syndrome (CRS), a disease of poor prognosis and severe sequelae. Global immunization programs and individual vaccination of women before their first pregnancy can prevent CRS.<sup>122</sup>

## Syphilis

The risk of syphilis during pregnancy parallels the rates of syphilis in women of childbearing age in a given population. All pregnant women should have a syphilis detection test at the first prenatal visit, and in many instances the test should be repeated one or more times to the time of delivery.<sup>123</sup> All seropositivity should be considered infection unless appropriate treatment can be documented and antibody concentrations decline. Since treatment in pregnancy both prevents and treats fetal infection, it is recommended without delay and consists of the penicillin regimen appropriate for the stage of syphilis diagnosed. Safe and effective alternatives to penicillin are not documented.<sup>124</sup>

 capsule of, 361  
 cell structure and extracellular products,  
 361–362  
 classification of, 356  
 clinical manifestations of, 356–360, 356b  
 epidemiology of, 356  
 exotoxins of, 357, 359, 360, 362  
 glomerulonephritis from, 360  
 in military populations, 1436  
 pathogenesis and immunology of, 360–362  
 pharyngitis from, 356–357, 359, 360, 362  
 reservoirs of, 356  
 rheumatic fever from, 356, 359–360  
 scarlet fever from, 357  
 soft tissue infections from, 357–358, 363, 366  
 toxic shock syndrome from, 358–359  
 treatment of, 362–363  
 drug resistance in, 362  
 virulence factors, 359, 360
- Streptolysins, 7  
 type O, 360, 361
- Streptomyces somaliensis*, mycetoma from, 892,  
 892t, 893  
 diagnosis of, 894  
 treatment of, 896f
- Streptomycin, 171t  
 in actinomycetoma, 895, 896f  
 in brucellosis, 467–468, 468b, 1448t  
 in plague, 479, 480  
 in tuberculosis, 174, 175t, 410–411, 411t,  
 1717  
 adverse effects of, 411  
 in initial regimen, 413  
 resistance to, 408, 409, 415, 416  
 in retreatment regimens, 416
- String test in strongyloidiasis, 1281

 diarrhea from, 1455  
 drug therapy in, 142, 144t, 1448t  
 eosinophilia from, 1484  
 historical descriptions of, 1274  
 in HIV infection, 1652–1653  
 life cycle and morphology of, 1274–1276,  
 1274f, 1275f  
 taxonomy of, 1274
- Strongyloides westeri*, 1274
- Strongyloidiasis, 1231, 1274–1282  
 agents causing, 1274–1275, 1274f, 1275f  
 arthritis in, 1280  
 autoinfection in, 1276–1278  
 clinical manifestations in, 1278–1281  
 in corticosteroid therapy, 1278, 1279, 1280f,  
 1281, 1282  
 diagnosis of, 1281, 1481t, 1491t  
 disseminated, 1276–1278  
 clinical manifestations in, 1279  
 diagnosis of, 1281  
 prevention of, 1282  
 treatment of, 1282  
 eosinophilia in, 1278, 1282, 1482–1484  
 diagnosis of, 1481t  
 epidemiology of, 1483  
 evaluation of, 1281, 1489–1490  
 magnitude of, 1482t  
 pulmonary, 1485, 1486, 1548  
 and skin lesions, 1488b  
 epidemiology of, 1275–1276  
 fever in, 1467  
 gastrointestinal disorders in, 1278,  
 1278f, 1279  
 diarrhea in, 1279, 1455  
 intestinal obstruction in, 1451  
 granuloma formation in, 1538  
 in HIV infection, 1280–1281, 1484, 1606,  
 1652–1653  
 and HTLV-1 infections, 1281, 1484, 1606,  
 1712  
 hyperinfection in, 1276–1278, 1484  
 clinical manifestations of, 1279  
 diagnosis of, 1281  
 in HIV infection, 1280–1281, 1652  
 prevention of, 1282  
 treatment of, 1282  
 in military populations, 1442  
 neurologic disorders in, 1279, 1280f, 1604t,  
 1606  
 pathogenesis and immunology in, 1276–1278  
 prevention and control measures, 1282
- Strongyloidiasis (*cont.*)  
 respiratory disorders in, 1279, 1485, 1486  
 diagnosis of, 1281  
 and eosinophilia, 1485, 1486, 1548  
 pathology in, 1278, 1279f  
 skin lesions in, 1279–1280, 1506t  
 and eosinophilia, 1488b  
 migratory, 1505, 1508t, 1509f  
 pruritic and urticarial, 1511t  
 treatment of, 142, 144t, 146, 1282, 1448t
- Strychnine poisoning, 487
- Subarachnoid neurocysticercosis, 1293, 1293f,  
 1295  
 treatment in, 1297, 1298
- Substance abuse  
 candidal infections in, 912  
 disseminated, 930  
 endocarditis in, 933  
 osteomyelitis in, 936  
 delusional parasitosis in, 1701, 1702t  
 hepatitis A in, 695  
 hepatitis B in, 700  
 hepatitis C in, 708  
 hepatitis D in, 714  
 HIV infection in, 853, 862, 874  
 in immigrant population, 1428t,  
 1429t, 1430  
 leishmaniasis in, 1646, 1647
- Sudan Ebola virus, 784, 785  
 clinical manifestations of, 790  
 epidemiology of, 786, 786t, 788f
- Sulbactam and ampicillin, 170t
- Sulfadiazine  
 in paracoccidioidomycosis, 920  
 in toxoplasmosis, 156, 158t, 1147  
 in HIV infection, 193t
- Sulfadoxine  
 in actinomycetoma, 895
